

HUMANS AS HOLOBIONTS: SYSTEMS-LEVEL APPROACHES FOR DISEASE PREVENTION AND THERAPY

Dissertation

in Partial Fulfilment of the Requirements for the Degree of
“Doctor of Philosophy” (PhD)

**Submitted to the Council of
the Faculty of Biological Sciences
of Friedrich Schiller University Jena**

**by M.Sc. Sara Leal Siliceo
born on July 6th, 1994 in Madrid**

This dissertation was prepared at the Leibniz Institute for Natural Product Research and Infection Biology e.V – Hans Knöll Institute (HKI), Jena in the Microbiome Dynamics Group under the supervision of Prof. Dr. Gianni Panagiotou. This project has received funding from the European Union Horizon 2020 Research and Innovation programme under the Marie Skłodowska-Curie grant agreement No 813781.

SUMMARY

The microbes that live in the gut, also known as the gut microbiota, play an important role in the well-being of the host. In the last years, the development of metagenomics and metabolomics have helped to better understand the vital role of the gut microbiome in human health and disease; however, the mechanisms and its implication are still not fully clarified. Therefore, more research and improved pipelines, protocols, and tools are needed to investigate gut microbiome in more depth and understand its connection with host health.

This dissertation aimed to develop and implement bioinformatic and statistical analyses to improve our understanding of the role of the gut microbiome in non-alcoholic fatty liver disease (NAFLD) pathogenesis. In addition, during my Ph.D. I focused on investigating novel microbiome-based therapeutic strategies.

NAFLD is the hepatic manifestation of a metabolic syndrome, and its prevalence has reached epidemic proportions with a global prevalence of about 32.4%. Previous works have demonstrated a link between gut microbiome dysbiosis and NAFLD progression. In this dissertation, three different projects have focused on investigating the role of the gut microbiome in NAFLD (**manuscripts I, III, and IV**). Due to the lack of pharmaceutical treatment for NAFLD, new strategies are being studied. In **manuscript I**, the effect of 4-month resistant starch (RS) supplementation as one type of microbiome-directed food was investigated in a cohort of NAFLD individuals. We showed that 4-month RS intervention ameliorates NAFLD, and multi-omics profiling provided an integrated understanding of how RS and associated alterations in the gut microbiota or metabolites contributed to NAFLD improvement. In addition, whole microbiota changes, the potential RS-targeted single species, and microbial metabolites were validated *in vivo* and *in vitro* for causal insights. The study has been accepted for publication in the journal **Cell Metabolism**, and will be published as the cover article of the journal.

In **manuscript IV**, the potential value of the gut microbiome in NAFLD prognosis was investigated, where differences in the microbiome signature and metabolic shifts in subjects that will develop NAFLD compared to controls were shown. In this project, potential microbial markers for NAFLD prognosis were identified and a machine learning model able to predict the development of NAFLD was developed. The study was published in the journal **Science Translational Medicine**.

Concerning the mycobiome, very little is known about how the fungal composition contributes to NAFLD progression. In **manuscript III**, a possible antifungal immunity and potential mycobiome dysbiosis were explored to investigate how intestinal fungi contribute to NAFLD development. Our results showed that NAFLD patients harboring a genetic variation in their IL-17A gene also presented increased *Candida* CTG species levels, and these two factors predispose to disease progression up to steatohepatitis (NASH) and advanced fibrosis. All these three projects together provide a more comprehensive understanding of the connection of the gut bacteriome, mycobiome, and metabolome changes with NAFLD development. Furthermore, novel microbiome-based therapeutic

techniques for NAFLD were explored, including a microbiota-directed food intervention and a NAFLD prognostic assessment tool.

Lastly, the utilization of lifestyle interventions targeting the gut microbiome to improve host health is a commonly used practice nowadays. A fourth study in this dissertation aimed to explore the gut microbiome dynamics in response to lifestyle microbiome-targeted therapies. In **manuscript II**, robust and generalizable biomarkers within the gut microbial communities that are associated with resistance to gut microbial community change were identified. Moreover, a machine learning model able to predict the gut microbiome resistance to change in response to lifestyle interventions using the baseline microbiome composition was developed. The study was published in the journal **Microbiome**.

In conclusion, in this dissertation, I have shown that the human body and its microbiome form a unity of life or holobiont that is indispensable for the well-functioning of the organism. The different bioinformatic analyses performed during my Ph.D. have highlighted the important role of the gut microbiome in human health and disease, especially giving new insights in relation to NAFLD pathogenesis and management. In addition, I have explored different microbiome-based strategies showing the high potential of the gut microbiome in the development of new therapies. Therefore, the use of microbiome-related information for patient therapeutics needs to be further explored and applied to improve and develop new and more personalized treatments.

ZUSAMMENFASSUNG

Die im Darm lebenden Mikroben, auch bekannt als Darmmikrobiota, spielen eine wichtige Rolle für das Wohlbefinden des Wirts. In den letzten Jahren hat die Entwicklung der Metagenomik und der Metabolomik dazu beigetragen, die wichtige Rolle des Darmmikrobioms für die menschliche Gesundheit und Krankheit besser zu verstehen. Dennoch sind die Mechanismen und ihre Auswirkungen noch nicht vollständig geklärt. Daher sind weitere Forschungsarbeiten und verbesserte Pipelines, Protokolle und Instrumente erforderlich, um das Darmmikrobiom eingehender zu untersuchen und seinen Zusammenhang mit der Gesundheit des Wirts zu verstehen.

Ziel dieser Dissertation war es, bioinformatische und statistische Analysen zu entwickeln und zu implementieren, um unser Verständnis der Rolle des Darmmikrobioms bei der Pathogenese der nichtalkoholischen Fettlebererkrankung (NAFLD aus dem Englischen) zu verbessern. Darüber hinaus konzentrierte ich mich während meiner Doktorarbeit auf die Erforschung neuer mikrobiombasierter therapeutischer Strategien.

Die NAFLD ist die hepatische Manifestation eines metabolischen Syndroms und hat mit einer weltweiten Prävalenz von etwa 32,4 % epidemische Ausmaße erreicht. Frühere Arbeiten haben einen Zusammenhang zwischen einer Dysbiose des Darmmikrobioms und dem Fortschreiten der NAFLD nachgewiesen. In dieser Dissertation wurde in drei verschiedenen Projekten die Rolle des Darmmikrobioms bei NAFLD untersucht (**Manuskripte I, III und IV**). Da es keine pharmazeutische Behandlung für NAFLD gibt, werden neue Strategien untersucht. In **Manuskript I** wurde die Wirkung einer 4-monatigen Supplementierung mit resistenter Stärke (RS) (eine Art mikrobiomgesteuerter Nahrungsmittel) in einer Kohorte von Personen mit NAFLD untersucht. Wir konnten zeigen, dass eine 4-monatige RS-Intervention die NAFLD verbessert, und die Multi-omics-Profilierung lieferte ein integriertes Verständnis dafür, wie RS und die damit verbundenen Veränderungen in der Darmmikrobiota oder den Metaboliten zur Verbesserung der NAFLD beitragen. Darüber hinaus wurden die Veränderungen der gesamten Mikrobiota, die potenziell auf RS abzielenden einzelnen Spezies und die mikrobiellen Stoffwechselprodukte *in vivo* und *in vitro* validiert, um kausale Erkenntnisse zu gewinnen. Die Studie ist zur Veröffentlichung in der Zeitschrift **Cell Metabolism** angenommen worden, und wird als Titelartikel in der Zeitschrift veröffentlicht.

In **Manuskript IV** wurde der potenzielle Wert des Darmmikrobioms für die NAFLD-Prognose untersucht, indem Unterschiede in der Mikrobiomsignatur und Stoffwechselferschiebungen bei Betroffenen, die NAFLD entwickeln werden, im Vergleich zu Kontrollen aufgezeigt wurden. Potenzielle mikrobielle Marker für die NAFLD-Prognose wurden im Rahmen dieses Projekt identifiziert und ein maschinelles Lernmodell vorgestellt, das die Entwicklung von NAFLD vorhersagen kann. Die Studie wurde in der Zeitschrift **Science Translational Medicine** veröffentlicht.

In Bezug auf das Mykobiom ist nur sehr wenig darüber bekannt, wie die Pilzzusammensetzung zum Fortschreiten der NAFLD beiträgt. In **Manuskript III** wurden

eine mögliche antimykotische Immunität und eine mögliche Mykobiom-Dysbiose untersucht, um herauszufinden, wie Darmpilze zur Entwicklung der NAFLD beitragen. Unsere Ergebnisse zeigten, dass NAFLD-Patienten mit einer genetischen Variation in ihrem IL-17A-Gen auch erhöhte Werte von Candida-CTG-Spezies aufwiesen, und diese beiden Faktoren prädisponieren für ein Fortschreiten der Krankheit bis hin zu Steatohepatitis (NASH) und fortgeschrittener Fibrose. Unsere Ergebnisse zeigten, dass NAFLD-Patienten mit einer genetischen Variation in ihrem IL-17A-Gen auch erhöhte Candida-CTG-Spezies-Spiegel aufwiesen, und diese beiden Faktoren prädisponieren für ein Fortschreiten der Krankheit bis hin zu Steatohepatitis (NASH) und fortgeschrittener Fibrose. Alle drei Projekte zusammen ermöglichen ein umfassenderes Verständnis des Zusammenhangs zwischen dem Darmbakteriom, dem Mykobiom und den Veränderungen des Metaboloms mit der Entwicklung der NAFLD. Außerdem wurden neuartige mikrobiombasierte therapeutische Verfahren für die NAFLD erforscht, darunter eine auf das Mikrobiom ausgerichtete Ernährungsintervention und ein Instrument zur prognostischen Bewertung der NAFLD.

Schließlich ist der Einsatz von auf das Darmmikrobiom abzielenden Lebensstilinterventionen heutzutage eine verbreitete angewandte Praxis zur Verbesserung der Gesundheit des Wirts. Eine vierte Studie in dieser Dissertation zielte darauf ab, die Dynamik des Darmmikrobioms als Reaktion auf mikrobiomorientierte Lifestyle-Therapien zu untersuchen. In **Manuskript II** wurden robuste und verallgemeinerbare Biomarker innerhalb der Darmmikrobiota identifiziert, die mit der Resistenz gegen Veränderungen der mikrobiellen Darmgemeinschaft in Verbindung gebracht wurden. Darüber hinaus wurde ein maschinelles Lernmodell entwickelt, das die Resistenz des Darmmikrobioms gegen Veränderungen als Reaktion auf Lebensstilmaßnahmen anhand der Zusammensetzung des Ausgangsmikrobioms vorhersagen kann. Die Studie wurde in der Zeitschrift **Microbiome** veröffentlicht.

Abschließend habe ich in dieser Dissertation gezeigt, dass der menschliche Körper und sein Mikrobiom eine Lebeneinheit oder einen Holobionten bilden, der für das gute Funktionieren des Organismus unerlässlich ist. Die verschiedenen bioinformatischen Analysen, die ich während meiner Doktorarbeit durchgeführt habe, haben die wichtige Rolle des Darmmikrobioms für die menschliche Gesundheit und Krankheit hervorgehoben und insbesondere neue Erkenntnisse in Bezug auf die Pathogenese und das Management der NAFLD geliefert. Darüber hinaus habe ich verschiedene mikrobiombasierte Strategien erforscht, die das große Potenzial des Darmmikrobioms für die Entwicklung neuer Therapien aufzeigen. Daher muss die Nutzung mikrobiombezogener Informationen für Patiententherapien weiter erforscht und angewendet werden, um neue und stärker personalisierte Behandlungen zu verbessern und zu entwickeln.

INTRODUCTION

1. The human microbiome

Microbes are microscopic organisms that are found in almost every environment and are essential to life. In the popular imaginary, they are generally linked with disease, however, most microbes are beneficial. They modulate key ecosystem processes and participate in functions such as plant growth, marine biogeochemical cycles, or food digestion (Malla et al. 2019). The human body is colonized by trillions of commensal, symbiotic, and pathogenic microorganisms that constitute the human microbiota, and the collection of genomes of an organism is known as the microbiome. The assembled of the host organism together with its microbiota is known as “holobiont” (Greek, from holos, whole; bios, life; -ont, to be; whole unit of life) a concept that was proposed by Lynn Margulis in 1991 (Thomas et al. 2017). Investigating the holobiont by exploring the interactions between the hosts and their associated microbial communities is crucial as it has been shown that the microbiota and the host mutually affect each other, being involved in health and disease development (Postler and Ghosh 2017). Therefore, the microbiome has an important role in regulating human health and functioning. This complex community is composed of bacteria (bacteriome), archaea (archaeome), fungi (mycobiome), and viruses (virome) (Lloyd-Price et al. 2016). However, to date, most of the studies have focused on the composition of the bacterial microbiota and their implication for human health, leaving the mycobiome, archaeome, and virome poorly understood (Matijašić et al. 2020).

Some of the large-scale international projects that strongly impacted microbiome research are the Human Microbiome Project (HMP) launched in 2007 and the EU FP7 METAGENOMICS of the Human Intestinal Tract (MetaHIT) project launched in 2008, financed by the National Institutes of Health (NIH) and the European Commission, respectively (Turnbaugh et al. 2007; Ehrlich 2011). Both projects helped to characterize the human-associated microbial communities and their alterations in different human pathologies. The HMP initially aimed to characterize the ‘healthy’ human microbiome, as well as the characterization of the microbiome of the different sites of the human body such as the skin, oral cavity, respiratory tract, gastrointestinal tract, urinary tract, etc (Nash et al. 2017). Since then, many studies have focused on investigating these two objectives. Numerous studies have shown that the different sites in the human body differ greatly in terms of their microbiome composition and functions (Lloyd-Price et al. 2016; Ward et al. 2018; Dekaboruah et al. 2020). In addition, characterizing the healthy microbiome and investigating the link between disease and the imbalance in the composition and function of microbial taxa, also known as dysbiosis, is crucial to determine the role of the microbiome in contributing to health and disease (Lloyd-Price et al. 2016; Koh and Kim 2017).

1.1 The gut bacteriome and mycobiome

The human gastrointestinal tract is a diverse and abundant microbial community made up of more than 100 trillion microorganisms, being the colon one of the most densely populated microbial habitats known on Earth (Rinninella et al. 2019). These digestive tract-associated microbes are known as the gut microbiome, and it is predominantly composed of bacteria. The mycobiome has been considered a minor component of the gut microbiota representing approximately less than 0.1% of the microbial community in the gut (Fotis et al. 2022). However, in the last years, the mycobiome has gained recognition as a fundamental part of the gut microbiome community (Zhang et al. 2021).

Due to its essential role in human health, the microbial community in the gastrointestinal tract has been widely studied as it is involved in host metabolism, immune system education and regulation, maintenance of structural integrity of the gut mucosal barrier, and protection against pathogen invasion (Jandhyala et al. 2015).

Several factors are involved in shaping the gut microbiota composition. For example, age has been proven to be a major contributor to differences in gut microbiota (Bosco and Noti 2021). Diet and the use of medication (e.g., antibiotics) are also considered to be key modulators of the gut microbial community (Valdes et al. 2018). The use of active microorganisms that colonize the human intestines and change the composition of the flora in particular parts of the host, also called probiotics, have been proven to play important roles in the gut microbiota community. Probiotics inhibit the colonization of pathogenic bacteria in the intestine, help the host to build a healthy intestinal mucosa protective layer, and enhance the host's immune system (Wang et al. 2021). In early stages of life, environmental factors such as the delivery mode or breastfeeding seem to have important effects on the microbial colonization of infants (Arrieta et al. 2014; Zhuang et al. 2019; Korpela 2021; Henderickx et al. 2022), and previous studies suggest that aberrant early microbial exposures have long-term immunological and metabolic consequences in the future development of the newborns (Yao et al. 2021).

2. The role of gut bacteria and fungi in metabolic diseases

In the last decades, the prevalence of metabolic disorders such as disturbed glucose metabolism, general and abdominal obesity, elevated blood pressure, dyslipidemia, insulin resistance, hyperglycemia, and hyperuricemia; has dramatically increased. These conditions are all risk factors for numerous serious diseases such as type 2 diabetes mellitus (T2D), non-alcoholic fatty liver disease (NAFLD), and inflammatory bowel disease (IBD), among others. The abnormally elevated levels of lipids in the blood or hyperlipidemia is also considered a high-risk factor and a key indicator of many metabolic diseases, and it has been reported to play a vital role in regulating host lipid metabolism (Jia et al. 2021). Therefore, in the last years, metabolic disorders have become a growing worldwide health challenge (Stephens et al. 2020).

The gut microbiota plays a role in regulating the host metabolism, and alteration of the gut microbiota's taxonomic composition and functions are associated with metabolic disorders (Magro et al. 2019; Glassner et al. 2020; Li et al. 2020; He et al. 2021). Microbiota changes including a decrease in diversity have been found in IBD subjects over time. A decrease in *Firmicutes* species and an increase in *Proteobacteria* species were seen in association with IBD (Glassner et al. 2020). In relation to fungal composition, *Candida* species were found to increase in IBD individuals compared to controls, whereas *Saccharomyces cerevisiae* levels decreased (Glassner et al. 2020). In subjects with Crohn's disease, a type of IBD, a lower microbial diversity compared to controls was also found (Magro et al. 2019). Furthermore, greater abundance in the *Proteobacteria* phylum and a reduction in *Akkermansia* and *Oscillospira* bacterial genera and *Saccharomyces cerevisiae* fungal species was identified in subjects with Crohn's disease (Magro et al. 2019). Obesity has also been associated with gut bacteriome and mycobiome dysbiosis (Rodríguez et al. 2015; Pinart et al. 2022). Lower relative proportions of *Bifidobacterium* and *Eggerthella*, and higher *Acidaminococcus*, *Dialister*, *Dorea*, *Prevotella*, and *Roseburia* were found in obese versus non-obese adults (Pinart et al. 2022). Concerning the fungal composition, an increased presence of the phylum Ascomycota and families Dipodascaceae and Saccharomycetaceae as well as an increase in the relative abundance of fungi belonging to the class Tremellomycetes were found in obese compared with non-obese subjects (Rodríguez et al. 2015). Along with bacteria and fungi, microbial communities like the virome are also altered in metabolic disorders including hypertension and T2D (Ma et al. 2018; Han et al. 2018). Therefore, investigating the complex interactions between different gut microbial communities may enhance our comprehension of disease development and progression.

Studies combining metabolomics and metagenomics are being used to elucidate the link between gut microbiota dysbiosis and metabolic disturbances, becoming a key focus of study in the characterization and progression of metabolic diseases (Agus et al. 2021). Specific kinds of microbiota-derived metabolites, such as short-chain fatty acids (SCFAs), branched-chain amino acids (BCAAs), aromatic amino acids (AAAs), or tryptophan have been implicated in the pathogenesis of metabolic disorders (Schnabl and Brenner 2014; Lavelle and Sokol 2020; Xiao et al. 2021). Ejtahed et al. found that the gut microbiota of obese individuals compared with lean controls may have a higher capacity for production of some SCFAs, branched-chain fatty acids (BCFAs), and AAAs, known as risk factors for some metabolic-related diseases (Ejtahed et al. 2020). Plasma concentrations of BCAAs are also frequently elevated in obesity and T2D (Cuomo et al. 2022). In addition, BCAAs (valine, isoleucine, and leucine) concentrations in plasma and urine were found to be associated with insulin resistance (Cuomo et al. 2022).

2.1 Non-alcoholic fatty liver disease and gut dysbiosis

Non-alcoholic fatty liver disease (NAFLD) is the hepatic manifestation of a combination of metabolic dysfunctions mainly characterized by insulin resistance, dyslipidemia, impaired glucose tolerance, abdominal adiposity, and hypertension, collectively known as

cardiometabolic syndrome (Younossi 2019). The main liver condition that characterizes NAFLD, as the name indicates, consists of too much fat stored in the liver cells in individuals who drink very little or no alcohol. NAFLD can evolve into non-alcoholic steatohepatitis (NASH), characterized by inflammation and fibrosis in the liver, and progressively lead to liver cirrhosis and hepatocellular carcinoma (Figure 1) (Younossi 2019). NAFLD is the leading cause of liver-related morbidity and mortality, being the most prevalent liver disease with an estimated global prevalence of up to 32.4% (Riazi et al. 2022). In addition, awareness about the disease among the general population is very low, and NAFLD is creating an extraordinary burden of clinical- and economic-related factors (Lazarus et al. 2022).

Figure 1 | NAFLD liver progression. Figure created with Biorender.

Even though the pathogenesis of NAFLD is not fully clarified, it is thought that dysbiosis, diet, genetics, and changes in intestinal permeability are risk factors that drive the progression from simple steatosis to NAFLD (Dongiovanni and Valenti 2017; Kolodziejczyk et al. 2019; Hu et al. 2020). Evidence has shown that the gut microbiome is closely related to the pathogenesis of NAFLD and contributes to the development of the disease via the gut-liver axis (Tripathi et al. 2018; Bauer et al. 2022). Boursier et al. investigated the changes in the microbiota in subjects with and without NASH and found that the bacterial genera *Bacteroides* and *Ruminococcus* were substantially increased, and *Prevotella* was reduced in patients with NASH (stage 2 fibrosis or higher) (16S) (Boursier et al. 2016). Loomba et al. studied the gut microbiota in patients with NAFLD with and without advanced fibrosis (stages 3 and 4) and showed an increased abundance of *Escherichia coli* and *Bacteroides vulgatus* in patients with advanced fibrosis (Loomba et al. 2017). Studies characterizing the intestinal microbiome in NAFLD have mostly focused on bacteria. Only one recently published study investigated the fungal community in the progression of NAFLD suggesting the mycobiome as a novel and relevant modulator of the development of the disease (Demir et al. 2022). In this study, Demir et al. identified that advanced NAFLD severity in non-obese subjects was associated with distinct fecal mycobiome signatures. In addition, there was an increased systemic immune response to *Candida albicans* in patients with NAFLD and advanced fibrosis. In **manuscript III** we

investigated the fungal changes and genetic variations in antifungal immunity in a NAFLD cohort, whereas in **manuscripts I and IV** bacterial changes together with metabolome shifts were evaluated in two different NAFLD cohorts.

Evidence of hepatic steatosis is needed in order to diagnose NAFLD. Histology (liver biopsy) and no-histology techniques (e.g., magnetic resonance spectroscopy, computed tomography, and ultrasonography) can be used to identify hepatic steatosis in the liver. Liver biopsy is considered the gold standard for NAFLD diagnosis; however, it can cause severe complications due to its invasive nature, and it is also prone to sampling error due to the unevenly distributed histological lesions (Herrema and Niess 2020). Some of the image-based diagnostic tools currently in use are magnetic resonance spectroscopy (MRS), computed tomography (CT), and ultrasonography. These techniques also have limitations such as high cost, radiation exposure, or limited accuracy. Among them, MRS has been considered the non-invasive standard method due to its highly accurate and reproducible diagnostic performance for evaluating NAFLD, and the no exposure to radiation (Lee 2017). However, the high cost and low availability make MRS remain primarily as a research tool not commonly used for clinical practice (Kechagias et al. 2022). Transient elastography (TE, FibroScan®) is an ultrasound-based technique to assess the liver stiffness (Piazzolla and Mangia 2020). TE with controlled attenuation parameter (CAP) simultaneously measures liver stiffness and fibrosis (Piazzolla and Mangia 2020). TE has been shown to have the best performance for the diagnosis and exclusion of advanced fibrosis when compared to liver fibrosis (Tovo et al. 2019).

New tools for NAFLD diagnosis combining non-invasive biomarkers are under investigation, as these seem to be the most promising cost-effective strategy. Numerous studies have explored non-invasive diagnostic approaches using clinically relevant biomarkers including non-invasive fibrosis models (e.g., fibrosis-4 index, NAFLD fibrosis score or stiffness, and AST/ALT ratio), clinical parameters (e.g., age, diabetes, and BMI), blood-based biomarkers (e.g., PRO-C3 and platelet count), and omics approaches (biomarkers that stem from genomics, transcriptomics, epigenomics, proteomics, lipidomics, and metabolomics). These emerging biomarkers can potentially be used in clinical practice and serve to develop novel diagnostic tools (Piazzolla and Mangia 2020; Hernandez Roman and Siddiqui 2020; Masoodi et al. 2021). **Manuscript IV** aimed to identify potential microbial biomarkers for early NAFLD detection and to develop a machine learning model that predicts the development of NAFLD 4 years before integrating metagenomics, metabolomics, and clinical data.

Regarding NAFLD medical strategies, there have been clinical trials investigating the effects of some drugs to treat NAFLD; however, to date there is no approved pharmacological treatment. Therefore, NAFLD pharmacological treatment used nowadays focuses on associated diseases such as diabetes, obesity, or lipid disorders to control patient glycemic status, liver injury, and lipid profiles (Jeznach-Steinhagen et al. 2019). Lifestyle interventions are currently the most effective strategy for managing NAFLD (Jeznach-Steinhagen et al. 2019). The importance of lifestyle has been recognized, and while potential pharmacological treatments are being tested in clinical trials, finding new strategies to stop

or slow down the progression of NAFLD is crucial. In **manuscript I**, a potential dietary intervention treatment was investigated in a cohort of NAFLD subjects.

3. Gut microbiome modulation

Given the significant contribution of the gut microbiome to a wide range of diseases, the human gut microbiota has become an attractive target for novel therapeutics, and the mechanisms shaping the gut microbiome are being studied. Determining cause-effect relationships and designing microbiome-based therapies that can produce specific outcomes on the microbial community and host health, are some of the biggest challenges in microbiome research (Wong and Levy 2019).

Different mechanisms may modulate the gut microbiota including clinical treatments (antibiotics, fecal microbiome transplant, probiotics, and pharmabiotics) and lifestyle interventions (exercise and diet) (Quigley and Gajula 2020).

Infections caused by pathogenic bacterial species are treated with antibiotics. Unfortunately, the current generation of antibiotics is broad-spectrum, which has a devastating impact on the commensal microbiota (Avis et al. 2021). Some of the major effects caused by antibiotics on the gut microbiota are the reduction of the species diversity, the alteration of the metabolic activity, and the development of bacterial antibiotic resistance (Ramirez et al. 2020). A meta-analysis of randomized controlled trials in children performed by McDonnell et al. showed that antibiotic exposure was associated with reduced microbiome diversity and richness, and with changes in bacterial abundance (McDonnell et al. 2021). Palleja et al. showed that 4 days of antibiotic treatment induced large shifts in bacterial abundances in adults (Palleja et al. 2018). Rashidi et al. demonstrated that specific microbiota signatures at baseline determine personalized microbiota responses to antibiotic perturbations in humans (Rashidi et al. 2021). In relation to the mycobiome, little is known about the effect of antibiotics on the fungal community. Antibiotic treatment has been shown to eliminate bacterial species that promote resistance against fungal colonization during homeostasis, leading to yeast overgrowth and fungal dysbiosis (Li et al. 2018). The overgrowth of *Candida albicans* species has also been linked to antibiotic intake (Shankar et al. 2015; Fan et al. 2015; Gutierrez et al. 2020). Interestingly, changes produced by antibiotics were found to be recovered in the bacterial community mostly over three months, while alterations in the fungal community were long-lasting (Seelbinder et al. 2020).

Fecal microbiome transplant (FMT) is a therapeutic strategy that involves administering specially prepared stool material from a donor into the intestinal tract of a recipient, aiming to alter the gut microbiota composition and improve the individual's health (Gupta et al. 2016). FMT has been used successfully as a treatment option in recurrent *Clostridium difficile* infection (Rohlke and Stollman 2012). Recently, the U.S. Food and Drug Administration (FDA) approved the first orally administered fecal microbiota product for the prevention of recurrence of *C. difficile* infection in individuals 18 years old and older (Carvalho 2023). The use of FMT in other microbiota-associated conditions that also experience gut microbiota dysbiosis such as NAFLD, diabetes, obesity, or IBD seems to be

a promising therapy but needs to be further investigated (Smits et al. 2013; Gupta et al. 2016; Napolitano and Covasa 2020).

Besides invasive solutions, exercise and microbiota-directed food interventions (MDFs) are the major gut microbial-modulation strategies that are being investigated for the treatment of a variety of human diseases associated with gut microbiome dysbiosis (Conlon and Bird 2015). In relation to exercise activity, Ni et al. showed that exercise in subjects with prediabetes was associated with differential gut microbiota changes, and these alterations were found to be linked with improvements in glucose homeostasis and insulin sensitivity. In addition, subjects that responded to the exercise intervention were found to have an enhanced capacity for generating SCFAs and an increased breakdown of BCAAs, whereas an increased production of metabolically detrimental compounds was associated with the microbiome of non-responders subjects (Liu et al. 2020). A different study in obese children showed that exercise training modulates positively the gut microbiota profile and produces changes reducing inflammatory signaling pathways induced by obesity (Quiroga et al. 2020). A recent investigation in subjects with NAFLD and prediabetes who underwent aerobic exercise combined with dietary intervention found that hepatic liver fat decreased in the intervention groups while increased in the control group; even more, the authors identified changes in the microbial alpha diversity and changes in the gut microbiota co-occurrence network (Cheng et al. 2022).

Regarding diet, microbiota-directed foods are known as aliments that aim to alter the structure or function of the gut microbiome and promote the growth of beneficial microbes associated with good health (Barratt et al. 2017). Numerous strategies making use of MDFs are being explored, for example, high fiber diet or low carbohydrate diet among others. Mardinoglu et al. found that the use of an isocaloric low-carbohydrate diet with increased protein promotes multiple metabolic benefits in obese humans with NAFLD (Mardinoglu et al. 2018). High-fiber diet intervention promoted the growth of SCFA-producing organisms in diabetic humans and induced changes in the microbiome community correlated with elevated levels of glucagon-like peptide-1, reduction in acetylated hemoglobin levels, and improved blood-glucose regulation (Zhao et al. 2018). A combination of low-fat/high-fiber diet was shown to improve the overall quality of life and decrease the inflammatory markers and dysbiosis in patients with ulcerative colitis (Fritsch et al. 2021).

3.1 Resistant starch as microbiota-directed food intervention

Non-digestible carbohydrates (NDCs) are fibers that are fermented by the gut microbes into SCFAs (Dobranowski and Stintzi 2021). Resistant starch (RS) is a type of NDCs that escapes digestion and survives passage through the stomach and small intestine to reach the colon where it is fermented by microorganisms (DeMartino and Cockburn 2020). Depending on their source and processing procedure, resistant starches are classified into five types (RS1–RS5). RS1 is physically unreachable starch, such as whole grains; RS2 is native granular starches, such as raw potatoes, green bananas, or high-amylose maize; RS3 is retrograded amylose starch or crystallized starch, such as cooked and cooled starchy

foods; RS4 is chemically modified starch; and RS5 is amylose-lipid complex (Zhu et al. 2022).

The use of resistant starch as microbiota-directed foods (MDFs) has become one of the focuses of non-digestible carbohydrate therapies for the prevention and treatment of obesity and related diseases (Zhang et al. 2015). The regulatory effects of RS supplementation on NAFLD mainly occur in the gut, where RS contributes to the restoration of the gut microbiota structure, the increase in SCFAs release, and the enhancement of the gut barrier integrity (Zhu et al. 2022). A recent meta-study showed that especially for diabetic overweight or obese subjects, RS supplementation can improve fasting glucose, fasting insulin, insulin resistance, and insulin sensitivity (Wang et al. 2019). RS supplementation showed improvements in clinical remission in patients with IBD (Montroy et al. 2020). Animal studies in mice also demonstrated RS to decrease adiposity, reduce insulin levels, and exert metabolic benefits (Higgins et al. 2011; Polakof et al. 2013; Rosado et al. 2020; Zhang et al. 2020; Montroy et al. 2020). Nevertheless, up to now, no clinical study has explored RS as a potential therapeutic treatment for NAFLD. In **manuscript I** the effects of RS2 from high-amylose maize in NAFLD subjects were investigated.

4. Resistance and resilience of the human gut microbiome

Gut microbiome responses to microbiome-targeted interventions are highly individual-specific (Olsson et al. 2022). This highlights the importance of investigating gut microbiome dynamics to better understand the mechanisms causing the microbiome to remain unaltered after the same perturbation and to determine whether is a microbial signature and specific taxa that are important contributors that contribute to the overall stability of the community (Risely 2020). Microbial stability is known as the property of maintaining a state of equilibrium and resist to perturbations to the community (Fassarella et al. 2021).

The use of metabolic engineering and synthetic biology will allow us to develop personalized therapies that target the gut microbiota. Identifying when a microbiome is not going to be affected by a microbiome-targeted therapy is crucial to develop personalized therapies to first alter the gut microbiome stability, so that it is sufficiently plastic to conduct a well-defined microbiome modulation treatment afterward. In addition, characterizing gut microbiome signatures associated with microbiome dynamics will also help to develop more precise patient stratification strategies combining host phenotype and microbiome stratification.

The gut microbiome is constantly fluctuating and trying to maintain a dynamic equilibrium over time while being exposed to external perturbations such as diet, medications, and the environment; that can disrupt the stability of the gut microbial ecosystem (Fassarella et al. 2021). However, to date, it is not clear how an individual microbial community responds to perturbations. External perturbations can lead to a transient dysbiotic state that will recover over time, but it can also lead to a stable dysbiotic state with negative implications for the host (Fassarella et al. 2021). To understand the response to perturbations in the gut as a complex ecosystem, it is important to distinguish

two concepts: resilience, which is the property of how fast or to what extent an ecosystem will recover its initial state after a perturbation; and resistance, that is the ability to remain unchanged during a perturbation (Sommer et al. 2017). An appropriate equilibrium state of resilience and resistance of the healthy gut microbiota protects us from dysbiotic-associated diseases (Sommer et al. 2017).

Even though the abundance of specific bacteria fluctuates over time, it has been shown that the gut microbial community in healthy subjects can be stable for years (Faith et al. 2013). In addition, gut microbial communities with higher diversity at the baseline showed more microbial stability over time (Chen et al. 2021). Chen et al. also observed that the genetic stability of gut microbes varies substantially across different species, and some species including *Ruminococcus torques*, *Streptococcus parasanguinis*, and *Faecalibacterium prausnitzii* were identified to be genetically unstable over time. A recent study in a Swedish healthy cohort showed that the gut microbiota functional potential is more stable than the species profile, and they identified that intra-individual compositional variability was negatively associated with the abundance of *Faecalibacterium prausnitzii* and two *Bifidobacterium* species (Olsson et al. 2022). Concerning diet, the stability of the microbiome composition was found to be correlated to dietary diversity, and food-microbiome interactions were identified to be highly personalized (Johnson et al. 2019). Hutchison et al. investigated the effect of a fermentable fiber diet in mice with different microbial communities, and their findings suggest that the effectiveness of a fermentable fiber diet in protecting against atherosclerosis is different for each animal and influenced by the composition of the gut microbiome (Hutchison et al. 2023). However, even though much research has been done on the effects of lifestyle interventions on the gut microbiome and human health, very little is known about how these lifestyle perturbations impact the stability, resistance, and resilience of the gut microbial community.

In **manuscript II** we explored the microbiome response to antibiotics and lifestyle treatments in order to characterize signatures associated with the gut microbial dynamics. We also developed a machine learning model that predicts the microbiome responsiveness in response to lifestyle interventions.

5. Bioinformatics approaches for studying the microbiome

The fast development of next-generation sequencing (NGS) technologies in the last decades has facilitated the rapid expansion of the microbiome field. Omics analyses including metatranscriptomics, metagenomics, proteomics, and metabolomics are some of the bioinformatic fields that have helped to understand and elucidate the role of the human microbiome in health and disease.

Metagenomic approaches allow the identification of microorganisms present in a sample. Thanks to the advances in NGS technologies, numerous metagenomic approaches are nowadays available to identify the composition of microbial populations. Amplicon sequencing and whole-genome shotgun (WGS) metagenomics are the two major methodologies for researching the microbiome utilizing high-throughput sequencing

(Figure 2) (Agus et al. 2021). In addition, the development of analyzing tools and resources, and the creation and curation of metagenome databases have widely increased in the last decade. Nowadays, a combination of different omics disciplines such as metagenomics and metabolomics has been suggested as a promising approach to study host–microbiome interactions (Turnbaugh and Gordon 2008), with a high potential to investigate metabolic-related disorders.

Figure 2 | Amplicon sequencing and whole-genome-shotgun sequencing (WGS) overview showing some of the most used tools and databases for each sequencing strategy. Figure created with Biorender.

5.1 Amplicon sequencing

To identify the microbial composition of a sample using sequencing strategies, it is not needed to sequence the full metagenome. A common practice, called amplicon sequencing, is to target a fragment of the genome. Amplicon sequencing uses generic primers designed to amplify a particular gene or gene fragment from all genomes present in a sample, and then the resulting product is sequenced. The rRNA regions commonly amplified for amplicon sequencing profiling are the 16S rRNA gene for bacteria/archaea, the 18S rRNA gene for eukaryotes, and the internal transcribed spacer regions 1 or 2 (ITS1/ITS2) of the fungal ribosome for fungi. This strategy generally involves four steps: DNA extraction, amplification of the marker gene through polymerase chain reaction (PCR) using target primers, barcoding of the amplicons of each sample with a short “barcode” sequence unique to each sample, and high throughput “multiplexed” sequencing of the combined amplicons from all samples in a single sequencing run (Dong et al. 2017).

Some of the generally used open-source amplicon analysis tools are QIIME2, DADA2, Mothur, and PIPITS. QIIME2 is a frequently used bioinformatics pipeline for performing microbiome analysis from raw sequencing data including demultiplexing and quality filtering, OTU picking, taxonomic assignment, phylogenetic reconstruction, diversity analysis, and visualizations (Bolyen et al. 2019). DADA2 is an R package that

implements the full amplicon workflow such as filtering, dereplication, chimera identification, and merging of paired-end reads (Callahan et al. 2016). Mothur is a software package for bioinformatics data processing that includes pre-processing, OTU picking, join reads, contig screening, taxonomic assignment, sequence filtering, chimera removal, etc (Schloss et al. 2009). Lastly, PIPITS is a stand-alone suite of software specifically for ITS data for automated processing of Illumina MiSeq sequences for fungal community analysis (Gweon et al. 2015). In order to perform the taxonomic assignment, it is essential the availability of reference databases. Some of the most used public reference databases for amplicon taxonomy assignment are SILVA for 16S/18S rRNA data (Quast et al. 2013), Greengenes for 16S rRNA data (DeSantis et al. 2006), and UNITE for ITS data (Nilsson et al. 2019).

In **manuscript III**, I used the PIPITS pipeline and UNITE database to process Illumina ITS1 sequencing data, and 16S sequencing data from **manuscript III** were processed using DADA2, QIIME2, and SILVA databases.

5.2 Whole-genome shotgun sequencing

In contrast to amplicon sequencing, shotgun metagenomics allows the sequencing of all accessible genomic DNA present in a given sample. WGS commonly consists of five stages: DNA extraction, random fragmentation of genomic DNA, genomic library preparation, paired-end sequencing, and genome assembly (Fuentes-Pardo and Ruzzante 2017). This strategy is a good taxonomic classification option due to the alignment of the whole genome and allows functional annotation providing an integrated understanding of the community structure, genetic population heterogeneity, and potential metabolism pathways (Niu et al. 2018).

Two popular tools for metagenomic taxonomic profiling are MetaPhlAn (Beghini et al. 2021) and Kraken (Wood and Salzberg 2014). Both tools are open source and include their curated database. MetaPhlAn uses clade-specific marker genes to study the microbiome taxonomic composition, while Kraken uses a K-mer based searching algorithm to assign taxonomic labels to the reads.

Functional profiling to identify the presence/expression of bacterial genes in the microbial community is also possible when analyzing shotgun sequencing data. HUMAnN (Beghini et al. 2021) is one of the most used tools for analyzing bacterial gene expression profiles. It allows to access different levels of information, being the reads first assigned to bacterial taxa and then searched against the protein databases for gene assignments. UnifRef database (Suzek et al. 2007) is used to identify gene families that then are mapped to different systems using the specific databases including MetaCyc reactions (Caspi et al. 2014), KEGG Orthologs (KOs) (Kanehisa et al. 2016), Pfam domains (Mistry et al. 2021), and Gene Ontology (GO) (The Gene Ontology Consortium 2021).

Whole-genome sequencing data were analyzed in **manuscripts I, II, and IV**. This allowed the taxonomical characterization of the microbial community as well as the functional profile. MetaPhlAn (versions 2 and 3) and HUMAnN (versions 2 and 3) tools were used to perform the taxonomic and functional profiling respectively.

5.3 Metabolomics

Metabolites are the intermediates or end products of multiple enzymatic reactions and therefore are the most informative proxies of the biochemical activity of an organism (Alonso et al. 2015). Metabolomics, known as the study of the metabolite composition within cells, biofluids, tissues, or organisms; has become an emerging technology in the last decades (Newgard 2017). There are two different metabolomic approaches: targeted and untargeted metabolomics, also known as validation-based or discovery-based, respectively (Schrimpe-Rutledge et al. 2016). Untargeted metabolomics focuses on global detection and relative quantitation of small molecules in a sample. In contrast, targeted metabolomics aims to measure quantitatively specific groups of metabolites; for this reason, prior knowledge of metabolites of interest and known compounds is needed (Schrimpe-Rutledge et al. 2016). Therefore, to perform targeted metabolomics analysis it is required to have a previously developed analytical method to measure the concentration of the specific metabolite in the sample (Shulaev 2006). Numerous metabolites cannot be identified with the currently available analytical techniques and purification standards, so targeted metabolomics cannot be used for novel metabolic markers identification (Shulaev 2006). Thus, targeted metabolomics is more quantitative, whereas untargeted often provides more information (Zhang et al. 2016).

Metabolomics has a wide range of applications being involved in numerous research areas including plant biotechnology, food technology, human diseases, and toxicology, among others (Gomez-Casati et al. 2013). One of the most growing areas is the biomedical field and the research of the metabolome in the development of human diseases, especially in metabolic-related disorders (Alonso et al. 2015). Metabolomics is facilitating the discovery of metabolite-disease biomarkers and in practice, it will enhance diagnosis, prognosis, surveillance, and personalized drug treatments (Gonzalez-Covarrubias et al. 2022). Albeit knowledge about the metabolites is crucial, integration of metabolomics with different omics disciplines may be a better approach to understanding many as yet undetermined disease mechanisms (Cambiaghi et al. 2017).

In this dissertation, targeted metabolomics data were analyzed in **manuscripts I and IV** from the two different NAFLD cohorts. Metabolomics changes and signatures were investigated, and metabolome-microbiome integration analyses were performed for better insights.

6. Statistical and machine learning techniques in metagenomics

Statistical analyses and machine learning workflows in this dissertation were performed using R programming language (R Core Team 2022) and R studio software (RStudio Team 2022). R is a very popular open-source programming language and environment, commonly used in statistical computing, data analytics, and scientific research, supported by the R Core Team and the R Foundation for Statistical Computing. RStudio is an open-source integrated development environment for the R programming language. It includes a console, syntax-

highlighting editor that supports direct code execution, as well as tools for plotting, history, debugging, and workspace management.

In order to perform comprehensive analyses and to have a full understanding of the different microbial communities analyzed in this dissertation, numerous bioinformatics data analysis techniques were applied to investigate and elucidate the different project objectives. Some of the main data analysis approaches that I applied during my Ph.D. are described below.

6.1 Methods for abundance comparisons

Identifying differentially abundant features such as bacteria, functions, or fungi is a common goal of metagenomics studies. New methods have been developed to identify changes in microbial abundances between different comparisons or conditions. Some of the commonly used tests or tools for differential abundance analysis are Wilcoxon test, generalized linear models (GLM), and metagenomeSeq.

Wilcoxon test is a non-parametric alternative to a t-test, appropriate when working with microbial data as commonly are non-normalized. Wilcoxon rank-sum test is used to compare two independent samples, while Wilcoxon signed-rank test is used to compare two related samples, matched samples, or to conduct a paired difference test of repeated measurements on a single sample (Schwaid 2017). Wilcoxon test can be performed in R using the function *wilcoxon.test* from the R package stats. Generalized linear model (GLM) is an advanced statistical modeling technique and is a basic method for advanced testing of differential abundance in sequencing data. GLM can model a mean response under non-linear, non-symmetric, and non-gaussian association conditions, where discrete and continuous data distributions can be fitted (Lu et al. 2019). The function *glm* from R package stats is used to fit generalized linear models. metagenomeSeq is a tool that was developed specifically for microbial datasets (Paulson et al. 2013) and was designed to determine microbial features that are differentially abundant between two or more groups of multiple samples. metagenomeSeq addresses the effects of both normalization and under-sampling of microbial communities on disease association detection and the testing of feature correlations. It is available in metagenomeSeq R package.

In addition, some of these methods allow accounting for covariates. It is known that the gut microbiome undergoes significant changes through age (Bosco and Noti 2021), and adjusting for age has been shown to improve the identification of gut microbial alterations (Ghosh et al. 2020). Other confounders affecting the microbiome composition that are commonly used when studying gut microbial changes are gender, ethnicity, or smoking among others (Chua et al., 2017; Jian et al., 2022; Loftfield et al., 2020; Si et al., 2021). The importance of considering covariates in microbiome studies will be addressed in the discussion section. From the previously mentioned methods, GLM and metagenomeSeq can perform differentially abundant analysis adjusting for covariates.

6.2 Methods for correlation analysis

Correlation is a statistical method used to study a possible linear association, connection, or relationship between two continuous variables. The statistic is called correlation coefficient, and it measures the strength and the direction of the relationship (Mukaka 2012). It ranges from -1 to 1 , with $+1$ indicating a perfect direct association, -1 , a perfect inverse association, and 0 , no relationship between the two variables, respectively (Mukaka 2012).

Three frequently used correlation methods in biostatistics are Pearson correlation, Kendall rank correlation, and Spearman correlation. These methods can detect linear or non-linear monotonic (strictly increasing or strictly decreasing function) relationships (Santos et al. 2014). We use Pearson correlation when both variables are normally distributed. For example, when we want to know if two clinical variables that are normally distributed have a linear association, we can perform a Pearson correlation between both variables. Pearson's correlation coefficient r is calculated as the covariance of the two variables divided by the product of their standard deviations. Unlike Pearson's correlation coefficient, Spearman's correlation rho (ρ) and Kendall's tau (τ) do not require the assumption of normality of the variables. Thus, these two correlation methods are more used when working with metagenomics data, as microbial data are rarely normally distributed. Spearman's correlation is a non-parametric test that does not carry any assumptions about the distribution of the data and is the appropriate correlation analysis when the variables are measured on a scale that is at least ordinal. It measures the degree of association between two variables. This method is simply the application of Pearson's correlation in the data converted to ranks before calculating the coefficient. Kendall's tau (τ) is another non-parametric test that measures the strength of dependence between two variables. In R, the function `cor.test` from the R package `stats` (R Core Team 2022) computes the Pearson's, Spearman's, or Kendall's correlation of two variables provided to the function.

In addition, it is also possible to compute correlation analysis between variables eliminating the effect of other covariates using the partial correlation approach. Partial correlation is defined as the association between two random variables after eliminating the effect of one or more other random variables. In R, the function `pcor` from the R package `ppcor` (Kim 2015) calculates the partial correlations of all pairs of two random variables of a matrix or a data frame for the different correlation methods previously described (Pearson's, Spearman's, and Kendall's).

6.3 Methods for network analysis

Network-based approaches are commonly used to explore -omics data. In metagenomics, microbiome network analyses allow us to understand community dynamics and explore the interactions and dependencies between the different members of the gut microbial community (Matchado et al. 2021). The complex interactions between thousands of individual taxa or functions and between different communities (e.g., bacteria, fungi, and metabolites), suggest network analysis as a powerful method in the microbiome field

(Matchado et al. 2021). Taxa and functions are common components modeled when performing gut microbial network analysis. These components in the network are known as nodes. When incorporating other types of data, nodes can also be host features, metabolites, genes, or proteins. The presence of an edge means that two nodes are connected, indicating an association between the two nodes. Correlation-based approaches, including Pearson or Spearman correlation previously described, are popular methods for studying these interactions (Jiang et al. 2019). However, in order to account for the compositionality of the microbial data, more specific tools such as SparCC and SPIEC-EASI have been developed to explore co-occurrence microbial networks. SparCC (Sparse Correlations for Compositional data) is one widely used method to build microbial community networks (Friedman and Alm 2012). This method was developed for estimating correlation values from compositional data. SparCC estimates the linear Pearson correlations between abundances in microbiome data accounting for their inherent sparsity and compositionality. It uses the centered log-ratio transformation to address data compositionality (Friedman and Alm 2012). SparCC was developed as a Python module, but there is also a reimplementation of the SparCC algorithm available using the R function `sparcc`. Another method developed to explore microbial networks is SPIEC-EASI (SParse InversE Covariance Estimation for Ecological Association Inference) (Kurtz et al. 2015). This method infers an ecological network (inverse covariance matrix) from compositional data using the log-ratio transformation and performs neighborhood selection and sparse inverse covariance selection (Kurtz et al. 2015). SPIEC-EASI pipeline was developed in R and can be run using the R function `spiec.easi` from the `SpiecEasi` package.

Once the microbial community network is built, we can explore the different characteristics of the network topology to investigate the connectivity and structure of the microbial ecosystem. Network metrics, such as degree centrality, betweenness centrality, closeness centrality, and hub score can be used to quantitatively describe these communities and identify the most important nodes (i.e., taxa) of a given community (Zamkovaya et al. 2021). Degree centrality measures the number of connections of a node (i.e., taxa or metabolite), and determines the level of co-occurrence of a node. Betweenness centrality is a measure based on the shortest paths and computes the extent to which a node lies on paths between others (Zamkovaya et al. 2021). Closeness centrality measures how far a node is from all other nodes and can be used to find the most central taxa of a given community network (Zamkovaya et al. 2021). Nodes with high degree and betweenness centrality are typically the most connected taxa within the community and are also known as “hubs” (Zamkovaya et al. 2021). These network characteristics provide essential insights into how specific features may contribute to ecosystem functioning.

Lastly, network clustering analysis allows the identification of densely connected nodes that form network subcommunities (or clusters) and reveals relationships among nodes in the community network. Clusters are powerful topological features to reflect network differences (Pan et al. 2021). Some clustering algorithms available in the R package `igraph` are Louvain, Walktrap, and Greedy clustering.

6.4 Machine learning

Machine learning (ML) is a branch of artificial intelligence that develops, analyzes, and implements predictive methods through the use of dynamic algorithms capable of data-driven decisions (El Bouchefry and de Souza 2020).

There are two main types of ML algorithms commonly applied to microbial datasets: supervised and unsupervised learning. In supervised learning algorithms, the output has been given a priori labels or the learner has some prior knowledge of the data, while in unsupervised learning algorithms, hidden patterns are identified in unlabeled data (Auslander et al. 2021). Some commonly used unsupervised algorithms include k-means clustering, hierarchical clustering, and principal component analysis. In the case of supervised learning, some examples of algorithms are random forest, support vector machines, and gradient boosting machines.

The development of a machine learning pipeline can be summarized in four main steps: data handling, model training, evaluation, and development (De Souza Nascimento et al. 2019). The data handling step includes different approaches such as data preprocessing and feature selection. Due to the importance of data quality in the model performance, it is crucial to implement an appropriate data handling approach when building a model. Feature selection is a key step to obtain an optimal and non-redundant subset of the initial features due to the extremely large number of features when working with microbiome data (e.g., species, genes, metabolites, etc.). Moreover, to evaluate and test the performance of a machine learning model, a resampling method called cross-validation is usually applied. Cross-validation uses different portions of the data to test and train a model on different iterations. Cross-validation together with feature selection are useful techniques that help to prevent one of the main problems when building a model, namely overfitting (when the model cannot generalize and fits too closely to the training dataset instead). To evaluate the performance of a machine learning model, different measurements are frequently computed including confusion matrix, accuracy, precision, specificity, sensitivity, receiver operating characteristic (ROC), and area under ROC curve (AUC).

The application of ML in the microbiome field is relatively new but it has shown a lot of potential for sophisticated analyses and generating new knowledge from the vast amount of omics data produced. Clinical data and gut microbial profiles from multi-omics analyses are used to develop ML models with different applications including phenotypic prediction, patient stratification, biomarker discovery, treatment outcome evaluation, and personalized treatment and nutrition (Li et al. 2022a). For instance, Franzosa et al. developed a machine-learning model using gut microbiome and metabolic profiles to classify subjects according to IBD phenotype (Franzosa et al. 2019). Zeevi et al. showed the power of the microbiome in personalized medicine and found that dietary, clinical, and anthropometric information together with microbial profiles can successfully predict postprandial glucose responses using a gradient boosting model (Zeevi et al. 2015). A recent study showed the potential of the combination of conventional risk factors and gut microbiome data for early risk stratification for liver disease (Liu et al. 2022). In this study, Liu et al. developed a gradient-boosting model able to predict liver disease 15 years before.

In this dissertation, caret R package has been used to implement machine learning pipelines. Caret is a powerful machine learning package that provides methods for common ML steps, such as preprocessing, training, tuning, and evaluating predictive models.

OBJECTIVES

This dissertation aimed to implement bioinformatic analyses making use of multi-omics techniques to expand the knowledge about the human gut microbiome and mycobiome and its implication for human health and disease. Complete study designs were set up for the different projects included in this dissertation to establish and perform meticulous analyses making use of state-of-the-art bioinformatics and statistical approaches to achieve the research objectives. During my research, I focused on investigating the role and connection of the gut microbiome and mycobiome in non-alcoholic fatty liver disease (NAFLD), and the effect of lifestyle interventions on the gut microbiome composition and dynamics.

Three research projects of this dissertation aimed to study the gut microbiome, mycobiome, and metabolome in NAFLD, and to evaluate different novel microbiome-based strategies for NAFLD. Using shotgun metagenomics (microbiome), ITS sequencing (mycobiome), and metabolomics; the characterization of the microbiome, mycobiome, and metabolome signatures in NAFLD progression was investigated. These projects served to ask the questions mentioned below:

1. Is resistant starch (RS) a beneficial microbiome-directed food intervention to treat NAFLD?
2. How the metabolome and gut microbiome of patients with NAFLD are altered after 4-month RS intervention?
3. Are there potential RS-targeted species or RS-targeted microbial metabolites?
4. In healthy people, is there a microbiome-metabolome signature able to predict the development of NAFLD and microbial biomarkers that serve as early detectors of NAFLD development?
5. How do intestinal fungi contribute to NAFLD progression?

A fourth study focused on investigating the resistance potential of an individual microbial ecosystem to lifestyle interventions. We performed a large-scale meta-analysis of metagenomic samples to better understand gut microbial dynamics and to identify potential microbial biomarkers associated with the microbiome resistance to lifestyle interventions. This project aimed to shed light on the following research questions:

1. How does the stability of the microbial community or the stability of the specific species respond to different antibiotic or lifestyle interventions?
2. Are there microbial biomarkers of community response that characterize the stability of the microbial composition of an individual?
3. Is it possible to predict the resistance of a microbiome community to be changed in response to a lifestyle intervention using the baseline gut microbial composition?

RESEARCH PUBLICATIONS

This cumulative dissertation consists of four research publications. Three first-author publications of which one is published in the journal *Microbiome* (**manuscript II**), another one is accepted for publication and will be the cover article in the issue of September of *Cell Metabolism* journal, and a third publication in preparation (**manuscript III**). Lastly, one co-author publication is published in the journal *Science Translational Medicine* (**manuscript IV**). Supplemental information of all published manuscripts can be downloaded from the websites of the respective publishers. Additionally, copies of these files are also included in the digital version of this dissertation. This dissertation comprises the following manuscripts:

➤ **Manuscript I:**

[co-first author] Ni Y, Qian L, Siliceo SL, Long X, Nychas E, Liu Y, Ismaiah MJ, Leung H, Zhang L, Gao Q, Wu Q, Zhang Y, Jia X, Liu S, Yuan R, Zhou L, Wang X, Li Q, Zhao Y, El-Nezami H, Xu A, Xu G, Li H, Panagiotou G, and Jia W., (in press). **Resistant starch decreases intrahepatic triglycerides in patients with NAFLD via gut microbiome alterations.** *Cell Metabolism*. [Accepted for publication in *Cell Metabolism* on June 13th].

➤ **Manuscript II:**

[co-first author] Chen J, Siliceo SL, Ni Y, Nielsen HB, Xu A, and Panagiotou G., (2023). **Identification of robust and generalizable biomarkers for microbiome-based stratification in lifestyle interventions.** *Microbiome*, **11**, 178. <https://doi.org/10.1186/s40168-023-01604-z>

➤ **Manuscript III:**

[co-first author] Thielemann N, Siliceo SL, Rau M, Herz M, Nieuwenhuizen N, Aldejohann AM, Hermanns HM, Mirhakkak MH, Löffler J, Dandekar T, Martin R, Panagiotou G, Geier A, and Kurzai O. **Genetic variation in IL-17A regulation and mycobiome dysbiosis contribute to non-alcoholic fatty liver disease.** [Manuscript in preparation].

➤ **Manuscript IV:**

[co-author] Leung H, Long X, Ni Y, Qian L, Nychas E, Siliceo SL, Pohl D, Hanhineva K, Liu Y, Xu A, Nielsen HB, Belda E, Clément K, Loomba R, Li H, Jia W, and Panagiotou G. (2022) **Risk assessment with gut microbiome and metabolite markers in NAFLD development.** *Science translational medicine*, **14**(648):eabk0855. <https://doi.org/10.1126/scitranslmed.abk0855>

Manuscript I

Resistant starch decreases intrahepatic triglycerides in patients with NAFLD via gut microbiome alterations

Overview

In manuscript I, we aimed to elucidate the effect of a resistant starch (RS) supplementation as one type of microbiome-directed foods (MDFs) to treat NAFLD and characterize the changes in the gut microbiome and metabolome during the intervention. Therefore, we conducted a randomized, double-blinded, placebo-controlled clinical trial of 4-month RS supplementation in individuals with NAFLD. Multi-omics profiling was used to provide an integrated understanding of how RS and associated alterations in the gut microbiota or

Graphical abstract

metabolites contributed to NAFLD improvement. Our results demonstrated the efficacy of RS as a novel microbiota-targeted intervention for NAFLD. Moreover, by performing multi-omics analyses tackling the complexity and heterogeneity of NAFLD pathogenesis, we identified possible mediators of the beneficial effect of RS. In addition, whole microbiota changes, the potential RS-targeted single species, and microbial metabolites were validated in mice and cell lines for causal insights.

40 **SUMMARY**

41 Non-alcoholic fatty liver disease (NAFLD) is a hepatic manifestation of metabolic
42 dysfunctions for which effective interventions are lacking. To investigate the effects of
43 resistant starch (RS) as a microbiota-directed dietary supplement for NAFLD treatment, we
44 coupled a 4-month randomized placebo-controlled clinical trial in individuals with NAFLD
45 (ChiCTR-IOR-15007519), with metagenomics and metabolomics analysis. Relative to the
46 control (n=97), the RS intervention (n=99) resulted in a 9.08% absolute reduction of
47 intrahepatic triglyceride content (IHTC), which was 5.89% after adjusting for weight loss.
48 Serum branched chain amino acids (BCAAs) and gut microbial species, in particular
49 *Bacteroides stercoris*, significantly correlated with IHTC and liver enzymes, and were
50 reduced by RS. Multi-omics integrative analyses revealed the interplay among gut
51 microbiota changes, BCAA availability, and hepatic steatosis, with causality supported by
52 fecal microbiota transplantation and monocolonization in mice. Thus, RS dietary
53 supplementation might be a strategy for managing NAFLD by altering gut microbiota
54 composition and functionality.

59

60 **INTRODUCTION**

61 An estimated 30% of the world's population currently has nonalcoholic fatty liver disease
62 (NAFLD), which has reached epidemic proportions globally^{1,2}. It is a multisystem disease
63 that may not only develop into severe chronic hepatic diseases but also contribute to
64 extrahepatic diseases such as type 2 diabetes, cardiovascular disease, and chronic kidney
65 disease, causing a tremendous clinical and economic burden^{3,4}. A recent large nationwide
66 cohort study with long-term follow-up showed significantly increased overall mortality with
67 all NAFLD histological stages including steatosis⁵, thus it is suggested that steatosis can no
68 longer be ignored as 'benign and an incidental finding'⁶. Although there have been clinical
69 trials exploring drug candidates, no pharmacological treatments have been approved for
70 NAFLD so far⁷. Hence, effective intervention strategies are urgently needed to delay or halt
71 its progression to related hepatic and extrahepatic diseases.

72 Accumulating evidence suggests that NAFLD is a disease closely related to gut
73 microbiota via the gut-liver axis^{8,9}, which stimulates the efforts to explore therapeutic
74 interventions to improve NAFLD by modulating the gut microbiota¹⁰. The safety and
75 persistence needed for microbiota-targeted intervention in humans highlights the
76 importance of exploring microbiota-directed foods (MDFs), which by definition can elicit
77 a targeted metabolic response in specific indigenous microbiota that confer a health benefit
78 on the host¹¹. Prebiotics and synbiotics like oligofructose and yogurt, which can manipulate
79 gut microbiota, were found to reduce insulin resistance, intrahepatic lipids, liver enzymes,
80 and histologically confirmed steatosis in patients with NAFLD/NASH¹²⁻¹⁴. Despite the
81 promise of MDFs in patients with NAFLD, such studies are in an early stage¹⁵. According
82 to the NAFLD practice guidance from the American Association for the Study of Liver
83 Diseases, rigorous, prospective, longer-term trials are required before making
84 recommendations about specific diets¹⁶. The complexity and heterogeneity of the NAFLD
85 pathogenesis calls for deep and extensive phenotyping to evaluate the multiple effects of an
86 intervention on NAFLD and their molecular mediators¹⁷. Furthermore, subsequent causal
87 investigations are needed to verify the specific microbial signatures identified in clinical
88 studies and their metabolites, which represent the highest levels in the chain of evidence in
89 microbiome-linked disease¹⁸.

90 In line with the above we performed here a randomized, double-blinded, placebo-

91 controlled clinical trial in individuals with NAFLD that lasted for 4 months to enable a
92 relatively long-term observation. We used as MDF resistant starch (RS), a prebiotic of
93 nondigestible fibers that are fermented in the large intestine¹⁹, which has been shown to
94 reduce adiposity and exert metabolic benefits in previous animal studies²⁰⁻²³, however so
95 far, no clinical study has investigated the therapeutic effect of RS on NAFLD.
96 Comprehensive clinical measurements were conducted to evaluate the changes in metabolic
97 phenotypes of NAFLD during the intervention. Multi-omics profiling was used to provide
98 an integrated understanding on how RS and associated alterations in the gut microbiota or
99 metabolites contributed to NAFLD improvement. In addition, the potential RS-targeted gut
100 species and microbial metabolites revealed by multi-omics analysis were validated in mice
101 and cell lines for causal insights.

104 RESULTS

105 Four-month RS intervention alleviates NAFLD in Chinese adults

106 To investigate the effects of RS on NAFLD, we conducted a randomized, double-blinded,
107 placebo-controlled clinical trial in Shanghai, China from 2016-March to 2017-October
108 (ChiCTR-IOR-15007519). A total of 200 participants with NAFLD (145 male and 55
109 female) were recruited and randomized with a 1:1 allocation to the 4-month administration
110 of RS type 2 from high-amylose maize (HAM-RS2, 40 g/day) or control starch (CS) with
111 equal energy supply (**Figures 1A and S1A**). The average age of all the participants receiving
112 randomization was 39.1 ± 9.1 years (mean \pm SD), while the average intrahepatic triglyceride
113 content (IHTC) was $24.12\% \pm 14.64\%$ (mean \pm SD). Both groups were counseled to manage
114 their diet following the standard menu designed by nutritionists. We measured the IHTC by
115 magnetic resonance spectroscopy (MRS) during interventions along with anthropometric
116 parameters and biochemical indexes. Four participants (3 in the CS group and 1 in the RS
117 group) did not receive the corresponding intervention after randomization and were
118 therefore excluded from the primary analysis (**Figure S1A**). Baseline anthropometric and
119 clinical characteristics of participants were balanced between the two groups (**Table 1**).
120 During the 4-month (120-day) intervention, the mean (\pm SD) percentage of the meals for
121 which participants adhered to starch intake was $84.0 \pm 16.1\%$ in CS and $83.8 \pm 12.6\%$ in
122 the RS group, with no significant difference (**Figure S1B**). Similarly, no significant
123 difference was found in the adherence to diet (**Figure S1C, Table S1**). Dietary intake of
124 energy and macronutrients except fiber were not significantly different between the two
125 groups (**Table S1**).

126 After the 4-month intervention, the primary outcome IHTC was significantly
127 decreased in the RS group compared to the CS group (-13.29% vs. -6.32% , $P < 0.0001$)
128 (**Figure 1B**). The net absolute and relative change of IHTC in the RS group relative to the
129 CS group was -9.08% (95% CI: -11.91% to -6.26%) and -39.42% (95% CI: -56.13% to $-$
130 22.72%), respectively (**Table 1**). Together with the alleviation of steatosis, we observed
131 significant reduction of body weight and BMI in the RS group compared to the CS group
132 (**Figure 1C**). The waist circumference, hip circumference, and waist-hip ratio (WHR) in the
133 RS group were all lower compared to the CS group. Regarding the body composition, the
134 reduction of fat percentage (FAT%) and fat mass (FM) were all significantly higher in the
135 RS group compared with the CS group (**Table 1**). The reduction of visceral fat areas (VFA)
136 and subcutaneous fat areas (SFA) evaluated by abdominal magnetic resonance imaging
137 (MRI) were significantly higher after RS consumption compared to CS consumption
138 (**Figures 1D and 1E**).

139 Furthermore, we observed significant reductions in alanine aminotransferase (ALT),
140 aspartate aminotransferase (AST), and gamma-glutamyl transpeptidase (GGT) after RS
141 intervention (**Figures 1F-1H; Table 1**), which indicate the improvements of liver injury.

142 The dyslipidemia was also alleviated by the RS intervention as shown in the improvement
143 of total cholesterol (TC), triglyceride (TG), low-density lipoprotein cholesterol (LDL-C),
144 and high-density lipoprotein cholesterol (HDL-C), which was absent after CS intervention
145 (**Table 1**). Notably, fibroblast growth factor 21 (FGF21), a generally acknowledged NAFLD
146 biomarker²⁴, was reduced after RS consumption (**Figure 1I**). The level of CK18 M65ED,
147 which correlates with hepatocyte apoptosis and independently predicts the presence of
148 NASH²⁴, was also significantly lower after RS compared to CS consumption (**Table 1**). In
149 addition, the circulating levels of lipopolysaccharides (LPS) and other inflammatory
150 markers including MCP-1, IL-1 β and TNF α , were all significantly reduced after RS
151 intervention in comparison to CS intervention (**Figure 1J-1M**).

152 While the fasting blood glucose level was reduced in both groups after the 4-month
153 intervention, neither fasting nor postprandial glucose levels during the meal tolerance test
154 demonstrated significant difference between the RS and CS intervention. Both the fasting
155 and postprandial insulin levels were significantly decreased in the RS compared to CS group,
156 as well as the insulin resistance evaluated by homeostasis model assessment (HOMA-IR)
157 and insulin resistance index of adipose tissue (Adipo-IR) (**Table 1**). Besides, the 4-month
158 RS consumption also resulted in cardiovascular improvements as the blood pressure was
159 significantly decreased compared to the CS consumption (**Table 1**). Due to dietary
160 management, significant reductions of adiposity and several metabolic parameters were also
161 observed in the CS group, albeit significantly smaller than the RS group.

162 We also performed a secondary analysis to adjust for the effect of weight loss. The net
163 absolute change of IHTC in the RS group relative to CS group after adjusting for weight
164 loss was -5.89% (95% CI: -8.87% to -2.91%), corresponding to a relative change of -24.30%
165 (95% CI: -42.42% to -6.18%), and remained statistically significant ($P = 0.0001$) (**Table 1**).
166 A regression analysis associating absolute change of IHTC with weight loss showed an R^2
167 of 23%, suggesting only a small part of the RS effect was mediated by weight loss. While
168 some clinical parameters showed weight loss-dependent changes, the changes of other
169 parameters related to adiposity (VFA), glucose metabolism (insulin levels, HOMA-IR,
170 Adipo-IR), lipid metabolism (TG, TC, HDL-C, LDL-C), hypertension (SBP, DBP), and
171 ALT all remained significant (**Table 1**). Moreover, we included all randomized participants
172 including four participants who did not receive the corresponding intervention in our
173 sensitivity analysis, and the conclusion remains the same (**Table S2**). Collectively, a 4-
174 month RS intervention reduced IHTC and improved liver injury and related metabolic
175 disorders in patients with NAFLD, even after adjusting for weight loss.

177 **RS intervention alters both fecal and serum metabolites in patients with NAFLD**

178 To investigate how the 4-month RS intervention affected the metabolism of the human host
179 and the commensal intestinal microbiota, we performed targeted metabolomics on serum
180 and fecal samples of participants in both the RS and CS groups before and after the
181 intervention. In total, we measured 30 amino acids (AAs) and 26 bile acids (BAs) in serum,
182 and 10 short chain fatty acids (SCFAs) and 18 BAs in feces. The RS and CS interventions
183 had different effects on the overall changes in measured metabolites ($P < 0.05$,
184 PERMANOVA) (**Figure 2A**). Examination of the different categories of metabolites
185 showed a small but significant change in both serum and fecal BA profiles ($P < 0.05$,
186 PERMANOVA).

187 At the level of individual metabolites, 13 metabolites among fecal BAs, serum BAs
188 and serum AAs were significantly changed ($P < 0.05$, Wilcoxon signed-rank test) by the RS
189 intervention but not the CS intervention (**Figure 2B**). No differences were observed in fecal
190 SCFA metabolites. All serum AAs with significant changes showed different directions of
191 change between the RS and CS groups. Interestingly, the serum levels of all three branched-
192 chain amino acids (BCAAs) (valine, leucine and isoleucine) decreased after the RS

193 intervention. The glutamate–serine–glycine (GSG) index, a possible marker of liver disease
194 severity that is independent of BMI²⁵, was also significantly reduced after the RS
195 intervention. In addition, we found 10 metabolites showing no differences at baseline to be
196 significantly different between the RS and CS groups at the end of the intervention ($P <$
197 0.05 , Wilcoxon rank-sum test), including valine, phenylalanine, and alpha-aminobutyric
198 acid.

199 Spearman's correlation analyses showed multiple strong, significant correlations
200 between the identified significant metabolites and patients' clinical parameters (**Figure**
201 **S2A**). To identify key metabolites and their possible relationships with NAFLD that were
202 independent of body weight, we repeated the correlation analyses, adjusting for clinical
203 parameters related to obesity, including BMI, waist circumference, VFA, SFA and body fat
204 percentage. This revealed multiple metabolites that significantly positively (alanine, valine,
205 leucine, and tyrosine) or negatively (aminobutyric acid) correlated with levels of human
206 IHTC (false discovery rate [FDR]-corrected $q < 0.1$) (**Figure 2C**). BCAAs and some BAs
207 including serum taurocholic acid (TCA) and serum glycocholic acid (GCA) were
208 significantly correlated with three NAFLD-relevant liver enzymes ALT, AST and GGT
209 (FDR-corrected $q < 0.1$). The serum levels of alanine, α -aminobutyric acid and valine
210 ($P=0.062$) also correlated with serum triglycerides (**Figure 2C**). Furthermore, the
211 correlations between BCAAs and IHTC, the primary outcome in our trial, remained
212 significant after controlling for obesity-related measures and insulin resistance (HOMA-
213 IR).

214 In summary, the RS intervention may exert its beneficial effects on patients with
215 NAFLD by altering the levels of microbial metabolic products, specifically the AAs pool
216 and BCAA levels available for the human host.

217

218 **The changes of gut microbiota upon RS intervention are associated with NAFLD** 219 **alleviation**

220 To investigate changes in the gut microbiota, we performed shotgun metagenomic
221 sequencing on fecal samples before and after the 4-month intervention for 50 participants
222 randomly selected from each group (matched with the full analysis set), generating 6.1 Gbp
223 of sequencing data on average (*s.d.* 1.3 Gbp per sample). While similar at baseline in alpha
224 (richness, Simpson index, and Faith's phylogenetic diversity) and beta diversity (weighted
225 or generalized UniFrac) based on MetaPhlan2 taxonomic profiling, significant differences
226 between the RS and CS groups were observed after the 4-month intervention ($P < 0.05$,
227 Wilcoxon rank-sum test for alpha and PERMANOVA for beta diversity) (**Figures 3A and**
228 **3B**). This result suggested different effects of RS on the overall gut microbiota community
229 compared to CS. Specifically, the RS group had lower alpha diversity than the CS group
230 after the intervention. This is consistent with many human and animal studies into the effects
231 of RS2 consumption, as reviewed before²⁶. Bendiks *et al.* also suggested the enrichment of
232 particular taxa, which can efficiently metabolize RS and its degradation products, as the
233 possible reason of decreased alpha diversity. In addition to the MetaPhlan2 profiling, we
234 used an approach relying on co-abundance gene groups (CAGs) to quantify the gut
235 microbiota composition. This led to the same findings for comparisons of microbiota alpha
236 and beta diversity (**Figure S2B and S2C**).

237 To uncover the bacterial species that were potentially associated with the beneficial
238 effects of the RS intervention, we adopted two approaches: a non-parametric Wilcoxon test
239 and generalized linear models. We focused on species that either significantly changed their
240 abundance after the RS treatment (but did not change after CS intervention) (**Figure 3C**) or
241 became significantly different in abundance between the two groups after the intervention
242 (with no differences at baseline). The non-parametric test revealed that the relative
243 abundances of 31 species significantly changed compared to the baseline or control group

244 (P < 0.05, Wilcoxon signed-rank test or Wilcoxon rank-sum test). The generalized linear
245 model found microbiota species that were significantly associated with the intervention,
246 while controlling for the effect of obesity-related measures. This analysis led to the
247 identification of species including *Bacteroides stercoris*, whose abundance was
248 significantly lower after the RS compared to the CS intervention (FDR-corrected q < 0.2)
249 (**Figures 3C and Table S3**). We correlated the abundances of all significant bacterial
250 species with a panel of clinical parameters, adjusting for obesity-related measurements, to
251 pinpoint the key species that were relevant to NAFLD (**Figure 3C**). We focused on the
252 bacteria that significantly correlated with important clinical features in NAFLD (IHTC,
253 ALT, AST, GGT and FGF21), and found *Bacteroides stercoris* correlated positively with
254 IHTC, ALT and AST. Significance remained (except P = 0.054 for AST) after further
255 adjusting for insulin resistance (HOMA-IR).

256 We next sought a deeper understanding of the bacterial-phenotype associations by
257 integrating them with the metabolomic profiles. We observed significant correlations
258 between the gut microbial community and the overall fecal BA and fecal SCFA profiles, as
259 well as the serum AA profile (P < 0.05, Mantel test). Moreover, significant associations
260 were found between microbiota composition and serum levels of valine, isoleucine and
261 leucine (P < 0.01, PERMANOVA). To further disentangle the interplay between gut
262 microbiota taxonomy and serum or fecal metabolite pools, we used Spearman's correlations
263 to link microbial species and metabolites with significantly differential abundances.
264 *Parabacteroides merdae*, whose abundance was significantly lower in RS than CS group
265 after intervention, had the highest number of significant correlations (mostly positive) with
266 multiple metabolites (**Figure 3D**). The RS-depleted intestinal microbe *B. stercoris*
267 correlated positively with serum valine level (P < 0.05, Spearman's correlation), which also
268 showed significant positive correlations with IHTC, ALT, AST, GGT and TG (**Figure 2C**).
269

270 **Transplantation of RS-altered gut microbiota alleviates NAFLD in mice**

271 To investigate the potential causality between RS-induced broad gut microbiota alteration
272 and reduction of hepatic steatosis, we performed fecal microbiota transplantation (FMT)
273 (**Figure 4A**) into conventional antibiotics-treated mice fed with high-fat high-cholesterol
274 (HFHC) diet, using samples from human donors after RS or CS intervention (whose changes
275 in IHTC after the intervention were close to the corresponding group average; n = 2 per
276 group). Compared to CS donors, FMT from RS donors led to significant reduction of the
277 body weight and liver weight (**Figures S3A-S3C**). Serum level of FGF21 was significantly
278 lower in the RS group, which was accompanied by the increased expression of FGF21
279 receptor, co-receptor, and adiponectin in the adipose tissue (**Figures S3D-S3F**).
280 Improvement of glucose metabolism, especially a significant increased insulin sensitivity,
281 was also observed in mice receiving fecal microbiota from RS donors (**Figures S3G and**
282 **S3H**). Histological assessments demonstrated significant decrease in hepatic steatosis,
283 ballooning, inflammation and NAFLD activity score after FMT from RS donors (**Figure**
284 **4B and 4C**). Moreover, the RS group had lower levels of liver enzymes ALT and AST,
285 hepatic TG, and total cholesterol in the liver (**Figure 4D-4G**). At the molecular level, FMT
286 from RS donors reduced the expression of marker genes in liver related to inflammation,
287 macrophage, and neutrophil recruitment (**Figure 4H**). It also reduced gene expression in
288 liver for lipogenesis and promoted the expression of genes related to lipolysis (**Figures 4I**
289 **and 4J**). Moreover, we also observed the improvement of gut barrier integrity as reflected
290 by the increased expression of genes encoding tight junction proteins (**Figure 4K**), together
291 with a significant reduction of serum LPS suggesting a possible alleviation of systemic
292 inflammation (**Figure 4L**). The levels of BCAAs in the colon content were also significantly
293 reduced in mice receiving FMT from RS donors than from CS donors (**Figure 4M**).

294 In addition to the wild-type mice, we also performed the experiment using a genetic
295 model of NAFLD, where *ApoE*^{-/-} mice were fed with HFHC diet followed by the same FMT
296 procedure. The causal effect of RS-mediated microbiome changes was successfully
297 replicated in the *ApoE*^{-/-} mice, including changes in body weight, liver weight, histological
298 scores, liver enzymes and serum FGF21 (**Figures S4A-S4H**). Consistent with the wild-type
299 mice, the *ApoE*^{-/-} mice receiving FMT from RS donors had decreased expression of
300 lipogenesis-related genes and increased expression of lipolysis-related genes in the liver, as
301 well as lower levels of colonic BCAAs (**Figures S4I-S4K**). Moreover, serum LPS was also
302 significantly reduced in the RS compared to the CS group, coupled by increased expression
303 of genes related to gut barrier integrity in the ileum (**Figures S4L and S4M**). In line with
304 the histological changes in inflammation, expression of inflammation-related genes in the
305 liver were effectively reduced (**Figure S4N**).

306 307 **Multi-omics integration analysis identifies key species associated with NAFLD** 308 **alleviation**

309 We profiled the functional potential of the gut microbiota and examined functional
310 differences in the RS and CS intervention groups. We found using the MetaCyc database
311 the relative abundances of 8 pathways to be significantly altered after the RS intervention
312 ($P < 0.05$, Wilcoxon signed-rank test) (**Figure S5A**). The microbiota functional potential
313 for starch degradation (MetaCyc PWY-6731) significantly increased after the RS
314 intervention ($P = 0.038$, Wilcoxon signed-rank test), but not in the CS group (**Figure S5B**).
315 In a particular category of gene families responsible for carbohydrate metabolism, we found
316 that 14 CAZy families were significantly altered after both the RS (**Figure 5A**) and CS
317 (**Figure S5C**) interventions ($P < 0.05$, Wilcoxon signed-rank test), with no common families
318 between RS and CS. Interestingly, a significant decrease was observed only after the RS
319 intervention in the abundances of the KEGG functional modules M00060
320 (lipopolysaccharide [LPS] biosynthesis, KDO2-lipid A, $P = 0.024$) and M00320 (LPS
321 export system, $P = 0.012$, Wilcoxon signed-rank tests) (**Figure 5B**). Another two LPS-
322 biosynthesis-related KEGG modules (M00063 and M00064) had significantly increased
323 abundances only after the CS intervention ($P = 0.017$ and $P = 0.023$, respectively, Wilcoxon
324 signed-rank test). As a proinflammatory bacterial compound, LPS can reduce intestinal
325 barrier function and increase translocation, and is demonstrated to accelerate hepatic
326 steatosis in NAFLD development²⁷. Moreover, *B. stercoris*-specific LPS biosynthesis
327 potential (M00060) was also significantly lower in RS than CS group after intervention (P
328 = 0.012, Wilcoxon rank-sum test).

329 The analyses above revealed several potential intestinal species/functions markers,
330 and signature metabolites related to NAFLD improvement after the RS intervention. To
331 uncover potential mechanistic links between changes in gut microbiota and NAFLD
332 alleviation, we applied a recently developed computational framework to integrate various
333 data types²⁸. Initially, we used a three-tiered analysis to screen out microbiota functions
334 (KEGG modules) that were significantly correlated with metabolites and important
335 phenotypes (IHTC, ALT, AST, GGT, and FGF21), while adjusting for obesity-related
336 parameters. These functions may serve as a bridge between the gut microbiota and host
337 metabolism and thus could be potentially related to NAFLD progression, such as the
338 biosynthesis and transport of various amino acids (tryptophan, histidine, lysine), cobalamin
339 (vitamin B12) and lipopolysaccharide (**Figure S6**). In the functional modules significantly
340 correlated with IHTC ($P < 0.05$, Spearman's correlation coefficient ≥ 0.2) in the RS group,
341 we identified four KEGG modules related to BCAA biosynthesis (**Figures 5C and 5D**),
342 emphasizing the strong relevance of BCAAs in NAFLD pathogenesis. Subsequently, gut
343 microbiota driver species analysis was performed to determine which species were the main
344 contributors of the function-phenotype associations. Overall, many more potential KEGG

345 modules (correlated to FGF21 or IHTC) and driver species were observed in the RS than in
346 the CS group, adding evidence that RS shaped the gut microbiome composition and activity
347 in a directed way (**Table S4**). In particular, we found three highly contributing driver species
348 involved in the correlations between the four BCAAs modules and IHTC (**Figure 5D**). *B.*
349 *stercoris*, the abundance of which was correlated with IHTC, ALT, AST and serum valine,
350 had the strongest driving effect on average of the four modules, especially M00019 for
351 valine/isoleucine biosynthesis.

352 To validate the positive association between *B. stercoris* and NAFLD, we re-
353 analyzed the metagenomic data from two published cohorts involving NAFLD (see
354 Methods). In a Chinese cohort²⁹, the abundance of *B. stercoris* was significantly higher in
355 patients with NAFLD than in NAFLD-free participants (**Figure 5E**). In a European cohort,
356 patients diagnosed by liver biopsy³⁰ with moderate or severe steatosis also had higher levels
357 of *B. stercoris* compared to mild steatosis or control (**Figure 5F**).

358

359 ***B. stercoris* promotes NAFLD progression partially through LPS and BCAA** 360 **production**

361 To examine a potential causal effect of *B. stercoris* on NAFLD progression, mice were
362 given a HFHC diet for 8 weeks to induce NAFLD, together with daily oral gavage of live
363 or heat-killed *B. stercoris* at 5×10^9 cfu/day along with the HFHC feeding (**Figure 6A**). Real-
364 time PCR showed a significantly increased amount of *B. stercoris* in the feces of the live
365 bacteria group compared with mice on the HFHC diet only (**Figure 6B**). *B. stercoris*
366 treatment showed no obvious effects on body weight or fat mass percentage (**Figures S7A-**
367 **S7B**), but significantly increased the liver weight percentage compared to control (**Figure**
368 **S7C**). Despite no obvious effects on either glucose or insulin levels in both fasting and fed
369 status, *B. stercoris* intervention for 8 weeks led to an impaired ability of the mice to dispose
370 glucose and decreased insulin sensitivity (**Figures S7D-S7G**). The serum level of ALT
371 increased 1.8-fold in mice gavaged with live *B. stercoris* while AST did not change
372 significantly (**Figure 6C and 6D**). By histological assessment, hepatic lipid accumulation,
373 inflammatory cell infiltration and fibrogenesis were all markedly enhanced in mice gavaged
374 with live *B. stercoris* (**Figures 6E-6J**) compared to mice only fed with HFHC. Consistent
375 with the histological observations, the level of hepatic TG was more than 2-fold higher in
376 mice gavaged with live *B. stercoris* (**Figure 6K**). Serum level of LPS was also significantly
377 increased after 8-week oral gavage (**Figure 6L**). To determine the specific impact of *B.*
378 *stercoris* at the molecular level, we explored the transcription of inflammatory and
379 fibrogenesis markers in liver tissues. In line with the higher histological scores, genes
380 involved in pro-inflammatory response, inflammatory cell infiltration, and collagen
381 formation were significantly higher in mice gavaged with live *B. stercoris* (**Figures 6M and**
382 **6N**). Collectively, these findings suggest that increased abundance of *B. stercoris*
383 contributed to NAFLD progression.

384 Besides live *B. stercoris*, heat-killed *B. stercoris* also showed ability to aggravate
385 NAFLD and elicited similar effects on inflammation, as reflected in the histological score,
386 ALT, serum LPS, and expression of genes involved in inflammation activation (**Figure 6C,**
387 **6H, 6L-6M**). Yet, the content of hepatic TG in mice with heat-killed *B. stercoris* showed
388 the trend to be lower than that in the live group ($P=0.054$) (**Figure 6K**).

389 Given the strong driving effect of *B. stercoris* in the correlations between gut
390 microbial BCAA biosynthesis and IHTC (**Figures 5C and 5D**), we then measured the fecal
391 levels of BCAAs in mice. We found the 8-week oral administration of live *B. stercoris*
392 significantly increased levels of fecal valine and isoleucine (**Figure 6O**). Unlike live *B.*
393 *stercoris*, mice daily gavaged with heat-killed *B. stercoris* showed only a minimal effect on
394 accumulation of fecal BCAAs, with similar pattern as steatosis score and hepatic TG
395 (**Figure 6F and 6K**). To further demonstrate a direct metabolic production of BCAA by *B.*

396 *stercoris*, we performed various cell cultures, with and without *B. stercoris* for different
397 time periods, followed by targeted metabolomics analysis of the cultured supernatant.
398 Compared with other groups, the cultured supernatant of live *B. stercoris* showed a
399 remarkable accumulation of BCAAs in a time-dependent manner, especially for valine
400 (**Figures 6P and S7H**).

401 The significant correlation identified in our clinical study between valine and IHTC
402 after controlling for obesity-related measures and HOMA-IR suggested a possible direct
403 influence of valine on liver fat accumulation and thus NAFLD pathogenesis. We therefore
404 investigated the direct *in vitro* effect of valine, which can be derived from NAFLD-
405 promoting *B. stercoris*, on lipid metabolism in HepG2 cells. Compared with incubation with
406 only fatty acid (FA), we observed a significant increase in intracellular TG content (**Figure**
407 **S7I**), and a dose-dependent increase in expression of the transcription factor SREBP1 and
408 lipogenic genes following incubation with valine (**Figure S7J**). Expression of FA
409 transporters and their corresponding transcription factors demonstrated similar dose-
410 dependent increases (**Figure S7K**). CPT1A, a gene involved in beta oxidation and lipid
411 catabolism, had lower expression following incubation with valine (**Figure S7K**).

412

413 **DISCUSSION**

414 The vital role of gut microbiota in liver diseases has been demonstrated by studies involving
415 FMT³¹ or single species such as *Roseburia intestinalis*³² and *Klebsiella pneumoniae*³³.
416 Such bidirectional relationship between the gut (and its resident microbiota) and the liver,
417 i.e., the gut-liver axis, has gained attention in the last several years with the hope of
418 developing microbiome-based strategies for diagnosis, prognosis and therapeutics of liver
419 diseases^{9,34,35}. However, the efficacy of most of the potential therapeutics for NAFLD needs
420 confirmation in well-designed human studies¹⁰. Previous clinical trials have demonstrated
421 the ability of MDFs to modulate human immune status³⁶ and to contribute to healthier
422 metabolic and growth profiles of undernourished children³⁷. In our randomized clinical
423 trial, we evaluated the effects of RS as a MDF for NAFLD treatment. To quantify changes
424 in liver fat content, we used MRI, a highly reproducible and the most accurate non-invasive
425 approach to detect hepatic steatosis^{24,38}. Several studies have also confirmed the superiority
426 of MRI over liver histology in assessing liver fat^{39,40}. It is more sensitive than histological
427 grading in detecting changes in liver fat over time⁴¹. Four-month intervention with this
428 MDF was effective in reducing IHTC in patients with NAFLD by an absolute reduction of
429 -5.89% and a relative reduction of -24.30% after adjusting for weight loss. Such effect was
430 partly mediated by altered composition and metabolic profile of gut microbiota. Indeed,
431 transfer of fecal microbiota from human donors receiving 4-month RS into mice fed with
432 HFHC diet reduced hepatic steatosis, lobular inflammation, and expression of lipogenesis-
433 and inflammation-related genes, suggesting a causal role of gut microbiota in alleviating
434 NAFLD. Moreover, expression of genes related to gut barrier integrity were enhanced while
435 the level of serum LPS was reduced in mice receiving FMT from RS donors. This is
436 consistent with decreased circulating level of LPS and the lower microbiota functional
437 potential for LPS biosynthesis in human participants after RS intake.

438 Amino acids were also identified as possible molecular mediators of the RS
439 beneficial effects. Perturbation in AA metabolism, especially aromatic amino acids (AAAs),
440 GSG index and BCAAs, has been shown to be involved in NAFLD and NASH pathogenesis
441^{25,30}. Serum levels of two AAAs, phenylalanine and tyrosine, were significantly lower after
442 RS than CS intervention; serum glutamic acid for GSG index calculation was significantly
443 reduced after RS intake (**Figure 2B**). Serum BCAAs has been associated with gut
444 microbiome alteration and insulin resistance⁴², which represents a NAFLD
445 pathophysiology. Here we observed consistent correlations between BCAAs and insulin
446 resistance, and the 4-month RS intervention in humans could significantly reduce the serum

447 levels of BCAAs. Furthermore, serum BCAAs were positively correlated with IHTC, ALT,
448 AST, and GGT. Importantly, the correlations between BCAAs and the primary outcome
449 IHTC remain significant after adjusting for obesity-related parameters and insulin
450 resistance, suggesting a direct influence of BCAAs on hepatic steatosis and thus NAFLD
451 pathogenesis. In the FMT experiment where transfer of RS-altered microbiota into mice
452 alleviated NAFLD, the colonic levels of BCAAs were also decreased, suggesting that the
453 change of gut microbiota caused by RS led to the change in BCAAs. The role of BCAAs in
454 hepatic steatosis was also supported by *in vitro* experiments investigating the direct effect
455 of valine on intracellular TG levels, through modulation of lipogenic transcription factors,
456 increased lipogenesis and decreased FA oxidation. Amino acids may modulate lipogenic
457 transcription factors through participating in the processing of enzymes and transcriptional
458 regulators as well as acting as substrates for lipid synthesis⁴³⁻⁴⁵. Elevated hepatic
459 lipogenesis is intimately involved in pathological consequences⁴⁵.

460 Apart from the causality between RS-induced broad gut microbiota alteration and
461 reduction of hepatic steatosis, we also attempted to pinpoint specific microbial species
462 involved in NAFLD development through multi-omics integration analysis. Among them,
463 we found RS reduced the abundance in the gut of *B. stercoris*, which is one of the species
464 highly correlated with IHTC, ALT and AST. These positive correlations remained
465 significant after controlling for obesity-related parameters and HOMA-IR, suggesting a
466 body weight- and insulin resistance-independent effect of *B. stercoris* on NAFLD
467 aggravation. The positive association of *B. stercoris* in the gut with NAFLD was further
468 validated in two independent external case-control cohorts from Asia and Europe (**Figures**
469 **5E and 5F**). In addition, *B. stercoris* was selected as a feature in a metagenome-based model
470 for predicting advanced fibrosis in US patients with NAFLD⁴⁶. Furthermore, we conducted
471 a monocolonization study to confirm the NAFLD-promoting effect of *B. stercoris* and to
472 explore the possible mechanisms involved. Oral gavage of both live and heat-killed *B.*
473 *stercoris* into mice could lead to increased lobular inflammation and enhanced expression
474 of genes involved in inflammation activation, which might be explained by the increased
475 serum level of LPS in both groups. On the other hand, considerably higher hepatic lipid
476 accumulation was only observed in the mice gavaged with live *B. stercoris*, which was
477 accompanied by the significantly higher levels of fecal BCAAs. Notably, the abundance of
478 *B. stercoris* in human participants was also found to positively correlate with BCAAs
479 (statistically significant for valine), and targeted measures of BCAAs in the monoculture
480 supernatant of live *B. stercoris* substantiated its BCAA-releasing activity. Altogether, it
481 suggests that *B. stercoris* can promote NAFLD progression, at least partially through LPS
482 and BCAA production.

483 The serum level of FGF21 was found to be significantly reduced after the 4-month
484 RS intervention. A number of preclinical and clinical studies demonstrate the robust effects
485 of FGF21 on alleviation of dyslipidemia and NAFLD^{47,48}. Contrary to the multiple
486 metabolic benefits of FGF21, circulating FGF21 is paradoxically elevated in individuals
487 with NAFLD^{49,50}. The concept of 'FGF21 resistance' was proposed to explain the
488 paradoxical changes of plasma FGF21 levels, in analogy to obesity-associated insulin and
489 leptin resistance⁵¹. Based on animal studies, aberrant FGF21 signaling has been suggested
490 as a key pathological step in the development and progression of NAFLD⁵². Notably, both
491 circulating and hepatic levels of FGF21 in obese mice were markedly reduced by exercise
492 training, where the FGF21 sensitivity in adipose tissue was enhanced⁵³. Besides engineered
493 human FGF21 analogues, the sensitization of the actions of FGF21 may represent an
494 alternative strategy for treatment of metabolic disorders⁴⁸. In line with this, here we
495 observed decreased serum level of FGF21 in participants after RS intervention and in mice
496 receiving feces from RS-fed donors, as well as increased expression of its receptor complex

497 and downstream effector in adipose tissue. Our findings suggested that RS-induced
498 microbiome changes might also lead to the sensitization of FGF21 actions.

499 Altogether, our study provides evidence that RS could be a novel, relatively simple
500 and inexpensive microbiota-targeted therapeutic option for NAFLD, which can reduce
501 IHTC by 5.89% in a weight loss-independent manner and decrease the liver enzymes
502 indicative of liver injury and markers for systemic inflammation. The change of gut
503 microbiota composition and functionality is an important mediator of the beneficial effect
504 of RS on NAFLD amelioration, including one gut microbe *B. stercoris* that aggravates
505 NAFLD at least partially through LPS and BCAA production. Our findings might contribute
506 to further understanding of NAFLD pathogenesis and the development of innovative
507 microbiome-based therapeutics or MDFs.

508

509 **Limitations of the study**

510 First, due to the lack of liver biopsy, we could not evaluate whether there were beneficial
511 histological changes in the liver, such as biopsy-proven steatosis, NASH or fibrosis.
512 However, our primary outcome was the change of liver fat content (hepatic steatosis) and
513 IHTC is considered to be more sensitive than the histological steatosis grades in quantifying
514 such changes, which has been recommended for clinical trial usage⁵⁴ and adopted by other
515 NAFLD intervention studies^{55,56}. Notably, the limitations of liver biopsy, including
516 invasiveness, sampling error, poor acceptability, and only moderate reproducibility, also
517 constrain its use as a repeat measurement to investigate histological changes in intervention
518 studies⁵⁷. Therefore, liver biopsy is not suitable for widespread use to assess disease stage
519 or determine progression or response to therapy⁵⁸. Second, in our randomized clinical trial,
520 dietary guidelines were offered to the enrolled patients and information on their dietary
521 intake was collected through questionnaires and further compared between the two
522 intervention groups. Similar studies in the future may use a standard identical diet to directly
523 control for the effect of diet as a potential confounding factor. Further research may reveal
524 other possible molecular mechanisms by which the RS-altered metabolites or gut microbes
525 lead to the accumulation or reduction of liver fat, the change of inflammation and fibrosis
526 in the liver.

527

528 **ACKNOWLEDGEMENTS**

529 We would like to thank all the medical staffs and study participants who took part in the
530 trial. The authors thank Prof. Jiarui Wu and Prof. Rong Zeng for the fruitful discussions,
531 and Dr. Ruben V. Uribe and Prof. Morten Sommer for help with the design of qPCR
532 primers. This work was supported by the National Natural Science Foundation of China
533 (NSFC) major international (regional) joint research project (81220108006), Shanghai
534 Municipal Key Clinical Specialty, Shanghai Research Center for Endocrine and Metabolic
535 Diseases (2022ZZ01002), and the National Key Research and Development Program of

Figure 2: Fecal and serum metabolomic changes after 4 months of resistant starch (RS) and control starch (CS) interventions. (A) Difference in overall changes of measured metabolome between RS and CS. Log₂-transformed fold-change profiles for all individual metabolites (serum and fecal) were used in partial least-squares discriminant analysis (PLSDA) and used to derive a Euclidean distance for statistical comparison between RS and CS with PERMANOVA. (B) Significantly changed fecal bile acids, serum bile acids and serum amino acids after the RS intervention (without significant changes after CS intervention) are shown. $P < 0.05$, Wilcoxon signed-rank test. X-axis represents z scores derived from Wilcoxon signed-rank test, for which positive and negative values indicate higher and lower abundance after the intervention, respectively. (C) Partial Spearman's correlation analyses between significant metabolites and patient clinical measures, adjusting for obesity-related clinical data (body mass index, waist circumference, visceral fat areas, subcutaneous fat areas, and fat percentage). Only serum metabolites significantly different between RS and CS groups at intervention end with no differences at baseline and with at least one significant correlation are shown. #, FDR-corrected $q < 0.1$ for individual metabolites. Circles, $P < 0.05$; solids dots, FDR-corrected $q < 0.1$. BA; bile acids; AA, amino acids; GLCA, glycolithocholic acid; GCA, glycocholic acid; DCA, deoxycholic acid; TUDCA, tauroursodeoxycholic acid; TCDCS, sulfated taurochenodeoxycholic acid; GUDCA, glyoursodeoxycholic acid; FINS: fasting insulin; FCP: fasting C-peptide. Figure 3: Compositional changes of gut microbiota after resistant starch (RS) intervention are associated with improvements in clinical phenotypes. Comparison of microbiota (A) alpha (richness, Simpson index, and Faith's phylogenetic diversity) and (B) beta diversity (weighted UniFrac distance) based on MetaPhlan2-derived taxonomic profiles. *, $P < 0.05$; **, $P < 0.01$. Wilcoxon signed-rank or rank-sum test was used for alpha

606 diversity comparisons; PERMANOVA was used to assess the statistical significance of beta
607 diversity comparisons. V1: visit 1 or baseline; V5: visit 5 or after 4-month intervention. (C)
608 Circos plot showing significant species in a phylogenetic tree and correlations with liver-
609 related parameters or biomarker. Significant species (solids dots, $P < 0.05$) refer to (i)
610 microbial species with significantly changed abundances after 4-month RS intervention but
611 not control starch (CS) ($P < 0.05$, Wilcoxon signed-rank test); or (ii) significantly different
612 species after 4-month RS intervention, controlling for effects of obesity-related measures
613 (BMI, waist circumference, visceral fat areas, subcutaneous fat areas, and fat percentage),
614 using generalized linear models. Partial Spearman's correlations were calculated between
615 significant species and patient clinical measures, adjusting for obesity-related clinical
616 measures. Surrounding boxplots show the abundances after RS and CS intervention, for
617 species with at least one significant correlation. (D) Spearman's rank-based correlations
618 between significant metabolites (from **Figure 2C**) and significant species (from **Figure 3C**).
619 After-intervention (V5) samples from both groups were used for correlation calculations.
620 Metabolites and species enriched in RS or CS groups are respectively, dark red or green.
621 Circles, $P < 0.05$; solids dots, FDR-corrected $q < 0.1$. Boxplots in (A) and (C) show median
622 (centerlines), lower/upper quartiles (box limits) and whiskers (the last data points 1.5 times
623 interquartile range (IQR) from the lower or upper quartiles). BA; bile acids; AA, amino
624 acids.

655 from the lower or upper quartiles). **(C)** Correlations between gut microbiota functional

656 modules and key clinical parameters or biomarkers of NAFLD. KEGG modules shown have

657 strong correlations (absolute Spearman's correlation coefficients ≥ 0.2) with intrahepatic

658 triglyceride content (IHTC) in the RS group. Red and blue indicate, respective, significantly

659 ($P < 0.05$) positive and negative correlations. *, FDR-corrected $q < 0.1$. **(D)** Driver species

660 for correlations between BCAA-related microbiota functions and IHTC. Species with

661 contributions higher than 10% effect towards function-IHTC correlations when removed in

leave-one-species-out analysis ($\text{pctSCCeffect.bgadj} > 10\%$) were considered driver species.

662 Only top contributing species for BCAA module-IHTC correlations are shown with their
663 driving effects illustrated in the Sankey plot. (E) Comparison of *B. stercoris* abundance in
664 a published Chinese cohort. (F) Comparison of *B. stercoris* abundance in a published
665 European cohort with liver biopsy. Data in (E) and (F) are log₂-transformed bacterial
666 relative abundances and compared with generalized linear model. Boxplots show median
667 (centerlines), lower/upper quartiles (box limits) and whiskers (the last data points 1.5 times
668 interquartile range (IQR) from the lower or upper quartiles).

Figure 6: Supplementation with *Bacteroides stercoris* promotes NAFLD progression in mice partially through BCAA production. (A) Schematic diagram showing the study design for *B. stercoris* intervention. (B) Abundance of *B. stercoris* quantified by qPCR with specific primers to determine fecal content for groups. Bacterial abundances are relative to control group. (C, D) Serum levels of ALT and AST. (E) Representative images of liver sections stained with H&E (scale bar, 200 μ m), Oil Red O (scale bar, 100 μ m) and Sirius Red (scale bar, 100 μ m). Arrows indicate inflammatory foci. (F-J) Quantification of

679 histological scores. **(K)** Quantification of hepatic triglycerides. **(L)** Serum level of LPS. **(M,**
680 **N)** Expression levels of genes involved in inflammation (M) and fibrogenesis (N) in the
681 liver. **(O)** Fecal levels of valine, isoleucine, and leucine by group. **(P)** Targeted
682 quantification of BCAAs by UPLC-MS/MS in culture supernatants of live or heat-killed *B.*
683 *stercoris* or culture media at different time points. For mice, data are mean \pm SEM. For B
684 and M-N, n = 2 technical replicates from 8 biological replicates for each group; For C-L
685 and O, n = 8 biological replicates for each group; for P, n = 3 biological replicates for each
686 group. *P < 0.05, **P < 0.01 and ***P < 0.001, based on one-way ANOVA (normally
687 distributed) followed by Tukey's post hoc test, or Kruskal-Wallis test (non-normally
688 distributed) followed by Dunn's test. In (P), * indicates the comparison between live and
689 control while # (#P < 0.05, ##P < 0.01 and ###P < 0.001) indicates the comparison between
690 live and heat-killed group. HFHC, high-fat, high cholesterol; BS, *Bacteroides stercoris*; HK,
691 heat-killed; AST, aspartate aminotransferase; ALT, alanine aminotransferase; LPS,
692 lipopolysaccharide.

696 Data are presented as mean (95%CIs). Four participants (3 in the CS group and 1 in the RS group) did
 697 not receive the corresponding intervention after randomization and were therefore excluded from
 698 analysis.

699 CS, control starch; RS, resistant starch; IHTC, intra-hepatic triglyceride content; CK 18, Cytokeratin 18;
 700 FGF21, fibroblast growth factor 21; BMI, body mass index; FM, fat mass; FFM, free fat mass; TBW,
 701 total body water; VFA, visceral fat area; SFA, subcutaneous fat area; SBP, systolic blood pressure; DBP,
 702 diastolic blood pressure; ALT, alanine transaminase; AST, aspartate transaminase; GGT, gamma-
 703 glutamyl transferase; TBIL, total bilirubin; DBIL, direct bilirubin; TBA, total bile acid.; BUN, blood urea
 704 nitrogen.; Cr, creatinine; UA, uric acid; RBP, retinol binding protein; TC, total cholesterol; TG,
 705 triglycerides; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol;
 706 NEFA, non-esterified fatty acid; MTT, meal tolerance test; PG, plasma glucose; AUC, area under curve;
 707 HOMA, homeostasis model assessment; Adipo-IR, adipose tissue insulin resistance index; LPS,
 708 lipopolysaccharide; MCP-1, monocyte chemoattractant protein-1; IL, interleukin; TNF α , tumor necrosis
 709 factor alpha.

710
 711 P value^a: Within-group differences were assessed using a linear mixed model.

712 P value^b: Differences in baseline variables between the RS and CS groups were assessed using Student's
 713 unpaired t-test.

714 P value^c: Differences in outcomes between the RS and CS groups were assessed using a linear mixed model.

715 P value^d: Differences in outcomes between the RS and CS group were assessed using a linear mixed model
 716 adjusted by weight loss and the baseline values of the variable assessed.

717

718 **STAR ★ METHODS**

719 **RESOURCE AVAILABILITY**

720 **Lead Contact**

- 721 • Further information and requests for resources and reagents should be directed to
722 the Lead Contact, Weiping Jia (wpjia@sjtu.edu.cn).

723

724 **Materials Availability**

- 725 • This study did not generate new unique reagents.

726

727 **Data and Code Availability**

- 728 • The raw metagenomic sequencing data for all samples have been deposited into
729 NCBI Sequencing Read Archive under accession number PRJNA703757.
- 730 • Computational analyses were performed using the bioBakery suite of tools including
731 MetaPhlAn2 (<https://github.com/biobakery/MetaPhlAn>; Methods) for microbiota
732 taxonomic profiling and HUMAnN2 (<https://github.com/biobakery/humann>;
733 Methods) for profiling of functional potential (ECs, pathways and modules).
- 734 • Source values used to create figures in the manuscript are available as Data S1.
- 735 • Any additional information required to reanalyze the data reported in this paper is
736 available from the lead contact upon request.

737

738

739 **EXPERIMENTAL MODEL AND PARTICIPANT DETAILS**

740 **Study participants**

741 A total of 200 individuals who met all the following eligibility criteria were recruited in the
742 Shanghai Jiao Tong University Affiliated Sixth People's Hospital. Inclusion criteria were:
743 (i) ethnic Chinese, (ii) liver steatosis diagnosed by ultrasonography, (iii) aged 18-70 years
744 old, and (iv) written informed consent obtained.

745 Exclusion criteria were: (i) participants with diabetes mellitus; (ii) alcohol
746 consumption history of more than 20 g per day for men and more than 10 g per day for
747 women; (iii) acute or chronic gastrointestinal diseases (including diarrhea, gastrointestinal
748 infection, inflammatory bowel disease), malignant tumor or severe renal dysfunction; (iv)
749 pregnancy, breastfeeding or planning to get pregnant; (v) consuming antibiotics within the
750 last 3 weeks or during the study; (vi) viral hepatitis, drug-induced liver disease, total
751 parenteral nutrition, Wilson's disease, autoimmune liver disease or other specific diseases
752 that can lead to fatty liver; (vii) routine use of prescription medicines or adjuvant Chinese
753 and Western medicines (except regular contraceptives); (viii) expected poor compliance;
754 (ix) use of weight loss medication or participation in weight-loss program in the past 3
755 months; (x) mental disorder preventing cooperation; or (xi) wearing pacemaker or metallic
756 implants, claustrophobia or other conditions that would be unable to undergo magnetic
757 resonance examinations.

758 The study was approved by the Ethics Committee of Shanghai Jiao Tong University
759 Affiliated Sixth People's Hospital, following the principles of the declaration of Helsinki.
760 All relevant ethical regulations were followed during the study. Written informed consent
761 was obtained from all participants. Complete clinical trial registration is deposited in the
762 WHO International Clinical Trials Registry Platform and Chinese Clinical Trial Registry
763 (<http://www.chictr.org.cn/showproj.aspx?proj=12353>; ChiCTR-IOR-15007519). The
764 primary indication was change in intrahepatic triglyceride content (IHTC), with changes in
765 anthropometric indicators, body composition, glycemic control and insulin sensitivity, liver

766 and renal function, lipid profiles, cytokines, multi-omic parameters, Single nucleotide
767 polymorphisms (SNPs), NAFLD remission rate, and percent change in intrahepatic
768 triglyceride content as secondary outcomes.

769

770 **Animal model**

771 All mice were housed in a specific-pathogen-free facility with a 12-h/12-h light/dark cycle
772 and given free access to food and water. All protocols for mouse experiments were approved
773 by the Committee on the Use of Live Animals for Teaching and Research of the University
774 of Hong Kong (CULATR No. 4361-17). All relevant ethical regulations were complied.
775 Mice involved in all experiments were given a HFHC diet (D12079B, Research Diets, New
776 Brunswick, NJ, USA) to induce NAFLD. For FMT experiments, 5-week-old male
777 C57BL/6J wild-type mice and 6-week-old male C57BL/6J *ApoE*^{-/-} mice were purchased
778 from GemPharmatech (Nanjing, China). Mice were randomly divided into two groups: RS
779 group and CS group (n =8 per group in the dietary model; n=6 per group in the genetic
780 model). Both were fed the HFHC diet for 11 weeks before fecal microbiota transplantation
781 (diet, water, and bedding were all sterilized). For *B. stercoris* gavage, eight-week-old male
782 C57BL/6J mice were randomly divided into three groups: HFHC with PBS group, HFHC
783 with live *B. stercoris* group, and HFHC with heat-killed *B. stercoris* group, and were treated
784 for 8 weeks. Body composition was assessed with a Minispec LF90 body composition
785 analyzer (Bruker, Billerica, MA, USA) after 8 weeks of feeding. Glucose and insulin levels
786 in both fasting and fed status, intraperitoneal glucose tolerance test, and insulin tolerance
787 tests were performed after 8 weeks of daily gavage⁵⁹.

788

789 **Culture and administration of *B. stercoris***

790 *B. stercoris* (catalog No. 19555, DSMZ-German Collection of Microorganisms and Cell
791 Cultures GmbH, Germany) was cultured in chopped meat medium (Hardy Diagnostics,
792 USA) at 37 °C in an anaerobic workstation (Gene Science AG300, China) with a gas mix
793 containing 10% hydrogen, 10% carbon dioxide and 80% nitrogen. The concentration of
794 bacteria was calculated by measuring the absorbance at the wavelength of 600nm. A fresh
795 culture containing 5×10⁹ cfu of *B. stercoris* in 200µL PBS was orally gavaged daily to
796 C57BL/6J mice, with sterile PBS as control. For one experimental group, *B. stercoris* was
797 heat killed at 121 °C under 225-kPa pressure for 15 min.

798

799 **Cell culture and treatment with valine**

800 Human hepatocellular carcinoma cells from the HepG2 cell line (ATCC, Manassas, VA,
801 USA) were cultured in Dulbecco's Modified Eagle Medium (Gibco, NY, USA) with 10%
802 fetal bovine serum (Gibco, NY, USA). This cell model demonstrated comparable results to
803 primary human hepatocytes in terms of lipid accumulation⁶⁰, which was the scope of our
804 *in vitro* study. Cells were kept in a 37°C incubator with 5% CO₂. Culture medium was
805 replaced every 2–3 days, and cells were sub-cultured upon reaching 80% confluence.

806 L-valine (TCI Chemicals, Portland, OR, USA) was dissolved in Milli-Q water to
807 form a stock solution and diluted with serum-free medium to working concentration (30-
808 750 µM). The concentration range for cell experiments was determined by the serum
809 concentration range from human clinical samples and preliminary cytotoxicity assays.
810 Sodium oleate (Sigma-Aldrich, St. Louis, MO, USA) was dissolved in water and sodium
811 palmitate (Sigma-Aldrich, St. Louis, MO, USA) in methanol for stock solutions. The stock
812 solution was further diluted with serum-free medium supplemented with 1% FA-free bovine
813 serum albumin (Gibco, NY, USA) to working concentration 1000 µM. FA-BSA complex
814 was prepared fresh before treatment.

815 For experiments, cells were plated on 6-well plates at 1×10^6 cells/well and allowed
816 to adhere overnight. Cells were incubated with valine for 24 hours followed by fatty acid
817 incubation for another 24 hours. Cells were then collected for further assays.

818

819 **METHOD DETAILS**

820 **Study design**

821 The study procedure has been detailed in the study protocol (**Methods S1**). Briefly, the
822 study was a randomized, double-blinded, placebo-controlled trial conducted at Shanghai
823 Jiao Tong University Affiliated Sixth People's Hospital from 2016-March to 2017-October.
824 Participants were randomized into two groups with an allocation ratio of 1:1 and consumed
825 either HAM-RS2 (Ingredion Inc., Bridgewater, NJ, USA) at 255.4 kcal/day (2.8 kcal/g, 91.2
826 g, containing 40 g RS) or matched CS (Ingredion Inc., USA) at 255.6 kcal/day (3.55 kcal/g,
827 72 g, containing 0 g RS) for 4 months (120 days). RS and CS were packaged in sealed bags
828 that were identical in appearance. During the entire trial, participants received dietary and
829 lifestyle counselling. All were engaged in light physical labor or had a sedentary lifestyle,
830 and were advised to keep their usual physical activity habits. Dietary counseling was
831 conducted by a trained dietitian. Standard menus with targeted dietary caloric restrictions
832 and macronutrient intake designed by the dietitian from the Department of Clinical
833 Nutrition, Shanghai Jiao Tong University Affiliated Sixth People's Hospital were provided
834 to participants, as well as the oilcan and scale. Participants were asked to fill in three
835 consecutive 24-hour dietary records (2 weekdays and 1 weekend day) at each visit period
836 and were encouraged to weigh foods to ensure they accurately reported their caloric intake.
837 In each visit, participants were met with a nutritionist individually for assessment of their
838 adherence to both the diet and the starches (adherence to diet was evaluated as whether the
839 total energy intake according to the 24-h dietary recalls met the requirement of diet
840 management; adherence to starch was evaluated by counting the empty packaging bags of
841 starch participants returned at each visit).

842 At each visit, participants came to the Department of Endocrinology and Metabolism
843 in the morning for collection of blood, urine and stool samples, and for the measurement of
844 anthropometric and biochemical indexes. Abdominal magnetic resonance imaging (MRI)
845 scan and MRS were conducted at V1 and V5, whereas meal tolerance tests were conducted
846 at V1, V3 and V5. The primary outcome was the change in IHTC evaluated by MRS.
847 Secondary outcomes were changes in anthropometric indexes, body composition, body fat
848 analysis by MRI, glycemic control, insulin sensitivity, liver and renal function, lipid
849 profiles, measurement of serum biomarkers, and other tests.

850 We recorded the combined medication during the follow-up visits and no
851 gastrointestinal drugs such as antacid were used. No serious adverse events were reported
852 throughout the study. Other potential intervention-related adverse events, including
853 constipation (8 participants in RS and 15 participants in CS, $P = 0.108$) and flatulence (20
854 participants in RS and 19 participants in CS, $P = 0.914$), were equally distributed between
855 the two groups, except the intestinal exhaust (35 participants in RS compared with 8 in CS,
856 $P < 0.001$).

857

858 **Anthropometric and biochemical measurements**

859 Blood pressure, body weight, height, waist circumference, and biomedical indices were
860 measured according to the study protocol (**Methods S1**). BMI (weight [kg]/ height² [m²])
861 was also calculated. Blood samples were collected from participants after an overnight fast
862 of at least 10 hours and were used to measure serum ALT, AST, GGT, TG, TC, HDL-C,
863 LDL-C, and non-esterified FA (NEFA). To assess the glucose metabolism, serial blood
864 samples were taken in a fasting state and at postprandial time points for laboratory tests of

865 plasma glucose, insulin and c-peptide after a standardized meal tolerance test (85 g of non-
866 fried instant noodles without soup: 376.98 kcal including 68.6 g carbohydrate, 9.4 g protein
867 and 6.8 g fat) (China Oil & Foodstuffs Corporation, China). Insulin resistance indexes were
868 calculated as follows: HOMA-IR = FPG (mmol/L) × FINS (mU/L)/22.5; Adipo-IR = fasted
869 insulin (mmol/L) × fasted NEFA (pmol/L).

870

871 **MRS examination**

872 Participants underwent liver MRS using the 3.0-T Philips Ingenia medical system (Philips
873 Healthcare, The Netherlands). Sagittal, coronal, and axial slices through the right lobe of
874 the liver were acquired, and regions of interest were selected by an experienced radiologist,
875 who avoided visible blood vessels and bile ducts. IHTC was measured in a single voxel (2
876 × 2 × 2 cm³) and calculated by dividing the integral of the methylene groups in fatty acid
877 chains of the hepatic triglyceride by the sum of methylene groups and water. The
878 experienced radiologists who performed the test were blinded to the clinical data.

879

880 **MRI examination**

881 Levels of SFA and VFA were determined by MRI using a 3.0-T Philips Ingenia medical
882 system (Philips Healthcare, The Netherlands) with spin echo sequences: 500/20 (TR/TE)
883 and matrix size = 256 × 25,659. Scan time was approximately 180 seconds. MRI scans were
884 obtained at the abdominal level between L4 and L5 vertebrae in the prone position. Analysis
885 of images was performed on a workstation provided by the manufacturer. MRI was
886 performed by experienced radiologists who were blinded to clinical presentation and
887 laboratory findings. Acquired images underwent measurement of SFA and VFA using a
888 semiautomated segmentation method. According to the signal intensity of adipose tissue,
889 SFA and VFA outlines were manually traced with a graphic user interface. The area inside
890 the outline was automatically labelled and calculated by the software SliceOmatic (Version
891 5.0, TomoVision, Canada).

892

893 **Diagnostic criteria for NAFLD**

894 We followed guidelines for the assessment and management of NAFLD in the Asia-Pacific
895 region. For all participants, NAFLD was diagnosed by B ultrasonography (detailed in study
896 protocol), ruling out secondary causes of hepatic fat accumulation including acute infectious
897 disease, biliary obstructive diseases, alcohol abuse (more than 20 g per day for men and
898 more than 10 g per day for women), acute or chronic cholecystitis, acute or chronic viral
899 hepatitis.

900

901 **Measurement of FGF21 and cytokerin 18 M65ED**

902 Concentration of FGF21 in human serum was quantified using an enzyme-linked
903 immunosorbent assay (ELISA) kit from Antibody and Immunoassay Services, the
904 University of Hong Kong (AIS, HKU, China). Human serum cytokerin 18 (CK18)
905 M65ED concentration was quantified with the M65 EpiDeath ELISA kit (Peviva AB,
906 Bromma, Sweden). Intra-assay variations for the measurement of FGF21 and CK18 M65ED
907 were 1.89% and 0.77%, respectively, and for inter-assay variations, these values were
908 4.08% and 8.23%.

909

910 **Measurement of LPS and pro-inflammatory factors**

911 Human serum LPS was measured by the Limulus Amebocyte Lysate assay (Hycult Biotech,
912 The Netherlands). Concentration of pro-inflammatory factors including IL6, IL1β, TNFα,
913 and MCP1 were quantified with ELISA kit (Invitrogen, USA). Intra-assay variations and
914 inter-assay variations for the measurements were all below 10%.

915

916 **Targeted metabolomics analysis of human fecal bile acids, serum bile acids and amino**
917 **acids**

918 *Sample pre-treatment*

919 For fecal samples, about 20-30 mg freeze-dried sample was added to 2 mL Eppendorf tubes.
920 One mL ethanol solution containing internal standards (CA-d5 0.3 µg/mL, CDCA-d4 0.9
921 µg/mL, GCA-d5 0.6 µg/mL, GCDCA-d4 0.6 µg/mL, TCA-d5 0.3 µg/mL, TDCA-d5 0.3
922 µg/mL) was added and vortexed. Subsequently, samples were ground with zirconia beads
923 (30 Hz, 1 min). After centrifugation (14,000 x g, 4°C for 10 min), 800 µL supernatant was
924 transferred for freeze-drying. Samples were then dissolved in 800 µL aqueous solution
925 containing 25% acetonitrile and filtered through a 0.22 µm filter membrane. For serum
926 samples, 50 µL sample was fully mixed with 200 µL acetonitrile solution containing internal
927 standards (CA-d5 0.1 µg/mL, CDCA-d4 0.3 µg/mL, GCA-d5 0.2 µg/mL, GCDCA-d4 0.2
928 µg/mL, GCDCA-d5 0.2 µg/mL, TCA-d5 0.1 µg/mL, TCDCDA-d5 0.1 µg/mL, TDCA-d5 0.1
929 µg/mL, alanine-d3 3 µg/mL, phe-d5 3 µg/mL, histine-¹³C₆ 1 µg/mL) for protein precipitation
930 and metabolite extraction. Supernatants were pipetted for freeze-drying. Finally, the powder
931 was dissolved in 70 µL aqueous solution containing 25% acetonitrile at 70 µL and 50 µL
932 redissolved solution was transferred into sample bottles. Another 10 µL was used for freeze-
933 drying for AA analysis.

934 Using the above 10 µL freeze-dried sample, derivative reactions were performed
935 with AccQTag derivatization kits (Waters, USA) before AA liquid chromatography (LC)-
936 MS analysis. Derivative reactions were performed according to the protocol and briefly
937 described as follows: 70 µL AccQ·Tag™ ultra-borate buffer (pH 8.8) was added to freeze-
938 dried samples and mixed for 30 seconds and 20 µL AccQ·Tag™ derivative reagent was
939 added after 10 seconds of vortex. The mixture was kept at room temperature for 1 min and
940 heated for 10 min at 55°C for derivatization reaction.

941

942 *LC-MS analysis*

943 For both BA and AA profiling, a high-performance liquid chromatograph Nexera X2
944 (Shimadzu, Japan) and triple quadrupole mass spectrometer (MS) 8050 (Shimadzu, Japan)
945 system equipped with electron spray ionization (ESI) ion source was employed. The main
946 MS parameters were: nebulizing gas flow at 3 L/min, heating gas flow at 10 L/min, interface
947 temperature at 300°C, DL temperature at 250°C, heat block temperature at 400°C, drying
948 gas flow at 10 L/min. Multiple reaction monitoring (MRM) was used to detect BAs and
949 AAs. ACQUITY UPLC C18 columns (100 mm × 2.1 mm, 1.7 µm) were used for
950 chromatograph separation.

951 Elution conditions for BA analysis were: Mobile phase A was 10 mM ammonium
952 bicarbonate aqueous solution and mobile phase B was pure acetonitrile. The gradient started
953 from 25% B and was maintained for 0.5 minutes, then linearly increased to 40% B in 12.5
954 minutes and 90% B in another 1 minute. The gradient was maintained at 90% B for 3
955 minutes, returning to 25% B in 0.5 minutes. The initial pre-equilibrium time was 2.5
956 minutes. Column temperature was 35°C. Flow rate was 0.35 mL/min. Injection volume was
957 5 µL.

958 Elution conditions for AA analysis were: The gradient started from 1% B, was
959 maintained for 1.08 min, and increased to 9.1% B in 10.4 min. At 16.3 min, the gradient
960 was linearly increased to 21.2% B, then quickly to 59.6% B in 0.6 min, and maintained for
961 1.2 min. The gradient was returned to 1% B in 0.18 min and maintained for 3.72 min for
962 initial pre-equilibrium. Column temperature was 55°C. Flow rate was 0.35 mL/min.
963 Injection volume was 0.1 µL.

964

965 **Targeted metabolomics analysis of fecal SCFAs**

966 *Sample processing*

967 About 20 mg feces sample and 200 μ L 50% acetonitrile/Milli Q water were mixed in an
968 Eppendorf tube. Samples were ground twice with zirconia bead (30 Hz for 1 min). After
969 centrifugation (14,000 x g, 4°C for 10 min), supernatants were collected and filtered, and an
970 aliquot of 40 μ L was transferred into 1.5 mL Eppendorf tubes following addition of 10 μ L
971 hexanoic acid -d11 (50 μ g/mL in 50% acetonitrile/MilliQ water). After vortexing, 20 μ L 3-
972 nitrophenyl hydrazine (200 mM in 50% acetonitrile/MilliQ water) and 20 μ L EDC (120
973 mM in 50% acetonitrile/MilliQ water containing 6% pyridine) were added. Tubes were
974 incubated in a water bath (40°C) for 30 min and placed on ice for 1 min to stop derivative
975 reactions. Before LC-MS analysis, 910 μ L 10% acetonitrile/MilliQ water was used for
976 dilution.

977

978 *LC-MS analysis*

979 Quantitative analysis used an AB SCIEX ExionLC AD UPLC coupled with AB SCIEX
980 triplequadrupole 6500 plus MS (AB SCIEX, Framingham, US). An ESI ion source was
981 used. MRM scan was operated in negative ionization mode. Ion source parameters were
982 capillary temperature 325°C, capillary voltage 49V and sheath gas 40 arb. An ACQUITY
983 UPLC C18 column (100 mm \times 2.1 mm, 1.7 μ m) was used for separation. Mobile phase A
984 was 0.1% formic acid in MilliQ water. Mobile phase B was 0.1% formic acid in acetonitrile.
985 The total run time was 11 min per sample. The gradient started from 15% B and was
986 increased to 27% B in 4 min, then to 42% B in 4 min, then 100% B in 0.5 min, maintained
987 for 1 min before returning to 15% B in 0.5 min and maintained for 1 min. Column
988 temperature was 40°C. Flow rate was 0.35 mL/min. Injection volume was 5 μ L.

989

990 **Fecal sample collection and DNA extraction**

991 Fecal samples were collected using a commercial tube with DNA stabilizer (STRATEC
992 Molecular, Berlin, Germany) and stored at -80°C. Stool DNA was extracted using PSP Spin
993 Stool DNA Kits (STRATEC Molecular, Berlin, Germany) according to the manufacturer's
994 instructions. Fecal DNA extracts were used to construct shotgun metagenomic libraries
995 using the KAPA soil kit following the standard protocol. The Novaseq 6000 platform was
996 used for 150 bp paired-end sequencing at Novogene, China.

997

998 **Quality control and taxonomic profiling**

999 For quality control of raw reads, human DNA contamination was removed using BWA *mem*
1000 version 0.7.4⁶¹ against human reference genome ucsc.hg19 and adaptors, low quality reads,
1001 bases or PCR duplicates were filtered as previously described³⁵. High-quality reads were
1002 taxonomically profiled at different taxonomic levels using MetaPhlan2⁶² version 2.7.7 with
1003 default settings, generating taxonomic relative abundances (total sum scaling
1004 normalization). For the CAGs-based approach, genes obtained from HUMAnN2
1005 ("Functional profiling" below) were clustered into CAGs and then metagenomic species
1006 (MGS, referring to CAGs with >700 genes) as described before⁶³ using default algorithm
1007 options. MGS were assigned a species-level annotation if more than 50% of genes were
1008 assigned the same species level taxonomy and if the second-most assigned taxonomy was
1009 <10% or unclassified.

1010

1011 **Microbial community diversity analysis**

1012 The alpha diversity was calculated using the R package *vegan*⁶⁴ and *picante*. Statistical
1013 comparisons of alpha diversity between groups were by Wilcoxon rank-sum test or signed-

1014 rank test using R package *stats*. Beta diversity (Bray-Curtis dissimilarity, weighted UniFrac
1015 and generalized UniFrac) was calculated with the R packages *phyloseq* and *GUniFrac*.
1016 Statistical comparison between groups was by the function *adonis* to perform a
1017 permutational multivariate analysis using R package *vegan* with 999 permutations. $P < 0.05$
1018 was considered significant.

1019

1020 **Functional profiling**

1021 Microbial gene families and pathway abundances were determined using HUMAnN2
1022 software⁶⁵ version 0.11.2 and the UniRef90 and MetaCyc databases. Gene families were
1023 mapped to Kyoto Encyclopedia of Genes and Genomes (KEGG) Orthology database
1024 included in HUMAnN2 to obtain KEGG modules and KEGG pathway abundances. Gene
1025 families were also mapped to level-4 enzyme commission (EC) categories using the EC
1026 database included in HUMAnN2. Carbohydrate-Active enZymes (CAZy)⁶⁶ were obtained
1027 by annotating ECs to the CAZy database. Tables of pathway and gene family abundance
1028 obtained using HUMAnN2 were normalized to copies per million, including unmapped and
1029 unintegrated reads.

1030

1031 **Integrating microbiome, metabolome and phenotypes**

1032 The omics computational framework described before²⁸ was used to perform a three-way
1033 analysis to screen potential KEGG modules that significantly correlated with metabolites
1034 and phenotypes, and leave-one-species-out analysis to determine the driver species of
1035 KEGG modules and important phenotypes. In the three-way analysis, correlations between
1036 the functional potential and phenotypes were by partial Spearman's correlation adjusting
1037 for obesity-related parameters. In cases of correlations between microbiota functional
1038 potential and metabolites, Spearman's correlation was used. In the leave-one-species-out
1039 analysis, we checked for KEGG modules with strong correlations (absolute Spearman's
1040 correlation ≥ 0.2) with IHTC or FGF21. Species with $> 10\%$ effect on the correlation after
1041 removal were deemed driver species.

1042

1043 **Validation of *B. stercoris* in external cohorts**

1044 Two independent external cohorts of different ethnicity were used. The Chinese cohort
1045 included 100 patients with NAFLD (diagnosed with ultrasonography) and 90 NAFLD-free
1046 control²⁹. The European cohort had different degrees of steatosis confirmed by liver biopsy
1047 controls³⁰, including 32 participants with no or mild steatosis and 24 participants with
1048 moderate or severe steatosis. The metagenomic data were processed with the above pipeline
1049 for quality control and taxonomic profiling.

1050

1051 **FMT Experiment**

1052 Mice were treated with antibiotics cocktail (ampicillin 1g/l, neomycin 1g/l, metronidazole
1053 1g/l, vancomycin 0.5g/l) for 7 days for microbiota depletion, followed by a 4-day wash-out
1054 period to eliminate antibiotics before fecal microbial transplantation as described previously
1055^{30,67}. Two human donors from RS or CS group who were close to the average change of
1056 IHTC within RS and CS intervention were selected for fecal microbial transplantations.
1057 Approximately 500 mg fresh human stools from each donor were collected in the anaerobic
1058 workstation and suspended in 5 ml PBS buffer containing 0.2 g/l Na_2S and 0.5 g/l cysteine.
1059 The mixture was homogenized and centrifuged, and the supernatant was collected under a
1060 stream of nitrogen. Stool samples from participants were not pooled, and fecal slurry from
1061 each donor was transferred into 4 conventional antibiotic-treated mice housed in one cage.
1062 The mice were colonized by oral gavage with 200 μl of RS or CS fecal slurry. Mice were
1063 treated once daily for three consecutive days by gavage in the first week of colonization,

1064 then fecal slurries were introduced every other day to reinforce colonization during the
1065 remaining days of the 3 weeks.

1066

1067 **Histological examination**

1068 Mouse liver samples were resected and fixed with 10% formaldehyde phosphate-buffered
1069 saline (pH 7.4), embedded in paraffin, sectioned, stained with hematoxylin/eosin (H&E,
1070 Sigma, USA) for morphology and Sirius Red (Abcam, UK) for fibrosis, followed by
1071 analysis with a Nikon DS-Ri2 microscope (Nikon Instruments Inc., Melville, USA). For
1072 detection of neutral lipids, liver cryosections embedded in OCT were stained with Oil Red
1073 O (Sigma, USA). Histology was evaluated by two independent researchers who were
1074 blinded to the experimental design and treatment groups according to the NAFLD scoring
1075 system as previously reported⁶⁸. In brief, 4 histological features were evaluated semi-
1076 quantitatively including steatosis (0-3), lobular inflammation (0-3), hepatocellular
1077 ballooning (0-2), and fibrosis (0-4). The unweighted sum of first three features was defined
1078 as NAFLD activity score (NAS).

1079

1080 **Biochemical assays in mice**

1081 Serum levels of AST, ALT, TC, TG, and glucose in mice were measured with commercial
1082 kits from Stanbio Laboratory (Boerne, TX, USA) or Nanjing Jiancheng Bioengineering
1083 Institute (Nanjing, China). Serum lipopolysaccharide (LPS) was measured by the Limulus
1084 Amebocyte Lysate assay (Hycult Biotech, The Netherlands). Insulin level was determined
1085 by immunoassay from Immunodiagnosics (AIS, HKU, China). Serum FGF21 in mice were
1086 measured by ELISA (AIS, HKU, China).

1087

1088 **Quantification of mice hepatic lipids**

1089 TG content of livers was determined by a modified Folch method⁶⁹. Briefly, 50 mg of liver
1090 tissue was homogenized in chloroform/methanol (2/1; v/v). After extraction at room
1091 temperature overnight, the organic phase was used to measure hepatic TG with commercial
1092 kits from Stanbio Laboratory (Boerne, TX, USA) or Nanjing Jiancheng Bioengineering
1093 Institute (Nanjing, China).

1094

1095 **RNA preparation and real-time quantitative polymerase chain reaction**

1096 Total RNA from livers or ileum was extracted with TRIzol reagent (Invitrogen, CA, USA),
1097 and total RNA from cells was extracted by RNAiso Plus reagent (Takara, Japan) according
1098 to the manufacturer's manual. RNA concentration was determined using a NanoDrop ND-
1099 1000 Spectrophotometer (Nano-Drop Technologies, Wilmington, DE, USA) and RNA
1100 quality was determined by the A260/A280 ratio of 1.8-2.1. RNA integrity was also checked
1101 by 1% agarose gel electrophoresis to ensure 2 intact bands of 28S and 18S RNA. Genomic
1102 DNA digestion and reverse transcription yielded cDNA from 1 µg RNA template using the
1103 HiScript RT SuperMix for qPCR kit (Vazyme Biotech, Nanjing, China) or PrimeScript™
1104 RT reagent Kit (Takara, Japan) according to the manufacturer's manual. Quantitative real-
1105 time PCR was performed using SYBR Green master mix on StepOnePlus Real-Time PCR
1106 system (Applied Biosystems, Foster City, CA, USA) or Light Cycler 480 system (Roche,
1107 USA). The mouse glyceraldehyde-3-phosphate dehydrogenase gene and human beta-actin
1108 gene were the reference for tests in mice or cell line, respectively. Relative changes in gene
1109 expression were calculated using the $2^{-\Delta\Delta CT}$ method. Primers used for PCR are listed in
1110 **Table S5**.

1111

1112 ***In vitro* testing of *B. stercoris* for valine releasing activity**

1113 *B. stercoris* was grown in the same culture medium as mentioned above to stationary phase
1114 and was inoculated to fresh medium that had been sterilized by an autoclave. Then the

1115 mixture was aliquoted and incubated under anaerobic conditions for 3, 5, 8, 12, 24 hours,
1116 respectively. At each time point, an aliquot was removed for centrifuging at 4500rpm (4°C
1117 for 15 min) to obtain culture supernatants. Following filtration (pore size 0.22 µm;
1118 Millipore, USA), the samples were stored at -80 °C until use. In parallel, fresh medium was
1119 aliquoted and incubated under the same conditions for the same period of time as blank
1120 control. At each time point, the supernatant was obtained from aliquot centrifuged at
1121 4500rpm (4°C for 15 min) as control.

1122 Experiments seeking to test whether heat-killed *B. stercoris* could produce valine
1123 were carried out by first incubating *B. stercoris* in medium at 37 °C under anaerobic
1124 conditions to stationary phase. Stationary phase culture was then treated at 121°C under
1125 pressure of 225 kPa for 15 minutes. And the culture was added to fresh medium. The
1126 mixture was incubated under anaerobic condition for 8h (logarithmic phase of growth of
1127 live *B. stercoris*) and then centrifuged to obtain culture supernatants.

1128 All cultures in each condition were performed in triplicate. An ultraperformance
1129 liquid chromatography coupled to tandem mass-spectrometry (UPLC-MS/MS) system
1130 (ACQUITY UPLC-Xevo TQ-S, Waters, USA) was used to quantitate all targeted
1131 metabolites by Metabo-Profile Biotechnology Co., Ltd ⁷⁰.

1132

1133 **Intracellular TG assays**

1134 Intracellular TG assays were performed using Triglyceride Colorimetric Assay Kits
1135 (Cayman Chemicals, Ann Arbor, MI, USA) according to the manufacturer's manual.
1136 Intracellular TG content was normalized to cellular protein quantified using Bradford
1137 Protein Assay (Bio-Rad, Hercules, CA, USA).

1138

1139 **Data visualization**

1140 Circos plots were made using interactive Tree of Life (<https://itol.embl.de/>). All other
1141 figures were generated by R software 3.6.3, using ggplot2 and ComplexHeatmap packages,
1142 or by GraphPad Prism 9.0.

1143

1144 **QUANTIFICATION AND STATISTICAL ANALYSIS**

1145 **Clinical and experimental data**

1146 For clinical data, analyses were performed with SPSS 25.0 (Chicago, IL, USA) and SAS
1147 version 9.4 (SAS Institute, Cary, NC, USA) as 2-sided with a significance level of $\alpha = 0.05$.
1148 Analyses were performed mainly in the full analysis set, which included all randomized
1149 patients who received at least one dose of study medication and had at least one post-
1150 intervention assessment of effectiveness. Numerical variables were expressed as mean (95%
1151 CIs). Categorical variables were expressed as percentages. Student's unpaired t-tests and
1152 chi-square tests were used for comparison between two groups at baseline. Linear mixed
1153 model was used to assess within-group differences. Comparison between the RS and CS
1154 groups at each visit was through analysis of covariance with treatment group as a factor and
1155 baseline value as a covariate. Differences in outcomes between the RS and CS groups were
1156 assessed using a linear mixed model. Fixed effects included baseline values of the assessed
1157 variable; treatment group (RS vs. CS as a categorical variable); categorical time points
1158 represented by 5 visits at days 0, 30, 60, 90, 120; and the interaction term of visit \times treatment
1159 group. Repeated measures were added as a random effect. Weight loss was used as an
1160 additional fixed effect when the weight loss-independent effect was assessed.

1161 For animal and cell line experiments, all analyses were performed with GraphPad
1162 Prism 9.0 (GraphPad Prism, USA). Data were shown as mean \pm SEM. Two-tailed Student's
1163 unpaired *t* test (normally distributed) or non-parametric Wilcoxon rank-sum test (non-
1164 normally distributed) was used for comparisons between two groups. Comparisons among
1165 more than two groups were performed using one-way ANOVA (normally distributed)

1166 followed by Tukey's post hoc test, or Kruskal-Wallis test (non-normally distributed)
1167 followed by Dunn's test.

1168

1169 **Metabolomics and metagenomics data**

1170 We performed partial least squares discriminant analysis using metabolite fold-change
1171 (log₂-transformed) profiles with the R package *mixOmics*⁷¹. Statistical comparison between
1172 groups was based on Bray Curtis dissimilarity using the function "adonis" in R package
1173 *vegan* with 999 permutations. Taxonomic and metabolite variations were further calculated
1174 as the ratio between microbial relative abundance or metabolite abundance at week 16
1175 against abundance at baseline. Log₂ transformation was applied to fold-changes. For
1176 taxonomic variation, before deriving fold-changes, zero values were additively smoothed
1177 by minimal nonzero abundance among all observed measurements. Differentially abundant
1178 species, functions and metabolites were identified by two-sided Wilcoxon rank-sum test or
1179 Wilcoxon signed-rank test, when appropriate, using R package *stats*. Z scores for
1180 metabolites variation were calculated using R package *rcompanion*. Generalized linear
1181 models were used to obtain differentially abundant species after adjusting for obesity-
1182 related parameters (species ~ group + VFA + SFA + BMI + Waist circumference + FAT%)
1183 with *glm* function from R package *stats*. To determine if metabolome and microbiome were
1184 associated, a mantel test was performed using the *mantel* function from the R package
1185 *vegan*. Bray-Curtis dissimilarity matrices based on the species and metabolite abundance
1186 tables were computed to perform this test.

1187 Spearman's correlation analysis was performed using R package *stats*. Partial
1188 Spearman correlation adjusting for obesity-related parameters (VFA + SFA + Waist
1189 circumference + BMI + FAT%) was performed between metabolites/species and clinical
1190 data using the R package *ppcor*. All statistical analyses were performed with R software
1191 3.6.3 and P < 0.05 was deemed significant unless otherwise stated. P values were adjusted
1192 by an FDR method⁷² using R package *stats*.

1193

1194

1195 **Data S1.** Source data underlying the display items in the manuscript, related to Figures 2–
1196 6, S2-S5, and S7.

1197

1198 **Table S4.** Species contributions to correlations between microbiota functional modules and
1199 intracellular hepatic triglyceride content (IHTC) or fibroblast growth factor 21 (FGF21) in
1200 resistant starch (RS) and control starch (CS) groups, related to Figure 5.

1201

1202 **Methods S1:** Study Protocol and statistical analysis plan, related to Figures 1-3, S1-2, and
1203 STAR Methods.

1204

RESEARCHOpen Access

Identification of robust and generalizable biomarkers for microbiome-based stratification in lifestyle interventions

Jiarui Chen^{1,2,3†}, Sara Leal Siliceo^{1†}, Yueqiong Ni¹, Henrik B. Nielsen⁴, Aimin Xu^{2,3,5} and Gianni Panagiotou^{1,3,6*}

Overview

In manuscript II, we aimed to investigate gut microbiome dynamics in response to lifestyle microbiome-targeted therapies and to identify robust and generalized biomarkers among the gut microbial communities associated with the resistance to change of the gut microbial community. Therefore, we performed longitudinal shotgun metagenomic analysis from a wide range of lifestyle interventions and defined a criterion to classify individuals based on the microbiome response using as a point of departure the natural fluctuation of a healthy microbiome without any intervention. We identified microbial biomarkers of microbiota's resistance to structural changes, and we found amino acid biosynthesis as an important regulator of microbiome dynamics. Lastly, we developed a machine learning model able to predict the gut microbiome resistance to change in response to lifestyle interventions using the baseline microbiome composition.

Identification of robust and generalizable biomarkers for microbiome-based stratification in lifestyle interventions

Abstract

Background A growing body of evidence suggests that the gut microbiota is strongly linked to general human health. Microbiome-directed interventions, such as diet and exercise, are acknowledged as a viable and achievable strategy for preventing disorders and improving human health. However, due to the significant inter-individual diversity of the gut microbiota between subjects, lifestyle recommendations are expected to have distinct and highly variable impacts to the microbiome structure.

Results Here, through a large-scale meta-analysis including 1448 shotgun metagenomics samples obtained longitudinally from 396 individuals during lifestyle studies, we revealed *Bacteroides stercoris*, *Prevotella copri*, and *Bacteroides vulgatus* as biomarkers of microbiota's resistance to structural changes, and aromatic and non-aromatic amino acid biosynthesis as important regulator of microbiome dynamics. We established criteria for distinguishing between significant compositional changes from normal microbiota fluctuation and classified individuals based on their level of response. We further developed a machine learning model for predicting "responders" and "non-responders" independently of the type of intervention with an area under the curve of up to 0.86 in external validation cohorts of different ethnicities.

Conclusions We propose here that microbiome-based stratification is possible for identifying individuals with highly plastic or highly resistant microbial structures. Identifying subjects that will not respond to generalized lifestyle therapeutic interventions targeting the restructuring of gut microbiota is important to ensure that primary end-points of clinical studies are reached.

Keywords Gut microbiome, Microbiome dynamics, Resistance, Lifestyle intervention, Machine learning

Background

The human gut microbiome is a complex ecosystem made up of trillions of bacteria, viruses, archaea, and eukaryotic microbes contributing to essential functions in the host. Emerging studies have shown the close connection between the gut microbiome and human health and disease [1], such as influencing host nutrition and metabolism, training and modulating immune function, and contributing to patterns of brain development and behavior. Gut microbiota dysbiosis has been associated with several highly prevalent chronic diseases including gastrointestinal and neurological [2–4] disorders, metabolic diseases, as well as cardiovascular and respiratory illnesses [5–7]. Therefore, targeting the gut microbiome seems to be a promising strategy for restoring balance in the gut in order to improve the host's health. However, unhealthy gut microbiota states can result in a recurring susceptibility to chronic illnesses and resistance to treatment efficacy [8].

Lifestyle interventions targeting the gut microbiota have been explored as a therapeutic treatment for numerous diseases. For example, prebiotic consumption, diet, and exercise have been associated with alterations in the gut microbiota structure and a positive impact on the host's phenotype [9–11]. In most trials, large inter-individual differences in the treatment response have been observed [8], and some of these differences may depend on subject-specific microbiome response to the perturbation. In most cases, the microbiome response is currently unpredicted. Consequently, gut microbiota stability, resilience, and resistance are crucial ecological features [12]. Therefore, it is urgent to understand the potential mechanisms involved in gut microbiome resistance that may govern the response to perturbations and to determine whether lifestyle interventions can shape gut microbiota composition towards resilient healthy states.

In order to shed light on the resistance potential presented by an individual gut microbial ecosystem, we performed a large-scale meta-analysis of metagenomics samples obtained from longitudinal lifestyle interventions and compared the responses with no-intervention and antibiotic treatment studies. Groups of “responders” and “non-responders” were defined by their magnitude of taxonomic changes to a diverse set of lifestyle interventions and characterized by distinct gut microbiota compositions and functional profiles. From a clinical and translational perspective, the ability to predict microbiome resistance to perturbation offers significant advantages to further optimize disease therapies through microbiome-informed patients' stratification and possibly restore plasticity in patients with resilient dysbiosis microbiomes.

Results

The extent of microbiome compositional changes depends on the environmental stimuli and varies between individuals

In order to elucidate the compositional and functional characteristics of the gut microbiome that may predict the personalized responses of the microbial communities to lifestyle, we collected metagenomic shotgun sequencing data from 10 studies covering 467 subjects sampled longitudinally (1590 total in total) (Table 1).

These included 1118 samples from subjects that did not undergo intervention. This allowed us to set a “response threshold” to differentiate between microbiome changes that could simply be considered as natural fluctuation, and significant alterations following various interventions. We also retrieved five cohorts with lifestyle-based treatment (165 subjects, 330 samples), including a low-carbohydrate diet with increased protein content (I_LCD); a high-fiber diet (I_HFD); a highly resistant starch type II (HRS); a multidisciplinary weight-loss program (I_MWP); and an exercise training program (I_ETP) (Table 1). Moreover, the dataset contains four cohorts with different antibiotic treatments (71 subjects, 142 samples): a cocktail of meropenem, gentamicin, and vancomycin (referred to from now on as A_MER–GEN–VAN); cefprozil (A_CEF); ciprofloxacin (A_CIP); and cotrimoxazole (A_COT). Taxonomic and functional profiling was performed with all samples from different cohorts simultaneously after passing through the quality control. Intraclass correlation coefficient (ICC) is a measure of reliability or reproducibility that can be used to quantify the biological variability of the microbiome structure, previously used by Sinha et al. [22] to compute the microbiome temporal stability. The genus-level ICC was calculated for different estimates of alpha (Shannon, Simpson, and Chao1 Index) and beta diversity (using the top principal coordinates analysis (PCoA) scores based on Bray–Curtis dissimilarity, and unweighted or weighted UniFrac distances) for every cohort in our study (Table S1). ICCs range from 0 (no stability) to 1 (perfect stability), where values below 0.5 indicate poor microbiome stability and above 0.5, high microbiome stability [23].

We observed significantly higher mean ICCs values of Shannon and Simpson diversities for the two no-intervention cohorts (that did not include any intervention) compared to the four cohorts treated with antibiotics as well as the five cohorts with lifestyle interventions (Student *t* test, $p < 0.05$, Fig. 1a). The average ICC values of the two no-intervention cohorts remained high (> 0.50) for all diversity indexes, suggesting a stable gut microbiome alpha diversity in the

Table 1 Description of the study cohorts used in the meta-analysis

Study	Disease	Intervention	Intervention information	Duration (days)	Number subjects/samples
Mehta et al., 2018 [13]	Healthy	No intervention	-	-	140/560
Poyet et al., 2019 [14]	Healthy	No intervention	-	-	91/558
Palleja et al., 2018 [15]	Healthy	Antibiotics	Meropenem, Gentamicin, and Vancomycin	4	12/24
Raymond et al., 2015 [16]	Healthy	Antibiotics	Cefprozil	7	18/36
Willmann et al., 2019 [17]	Hematological-Oncological disease	Antibiotics	Ciprofloxacin Cotrimoxazole	6	20/40 21/42
Louis et al., 2016 [18]	Obesity	Exercise/Dietary	Multidisciplinary weight-loss program (OPTI-FAST® 52, Nestlé Inc.): psychology, medicine, dietetics (very low-calorie diet), and exercise	84	14/28

Zhao et al., 2018 [20]	T2D	Dietary	High fiber diet composed of whole grains, traditional Chinese medicinal foods, and prebiotics	84	71/142
Ni et al., (in press) [21]	NAFLD	Dietary	Diet with high resistant starch type II content	120	50/100
Liu et al., 2020 [9]	Prediabetes	Exercise	Exercise activity 3 days/week as a combined aerobic and strength training program	84	20/40

absence of external disturbances. Interestingly, there is no significant difference in mean ICCs values of any alpha diversity index when comparing the four cohorts treated with antibiotics and the five cohorts undergoing lifestyle interventions (Student *t* test, $p=0.14$, 0.240, 0.052 for Shannon index, Simpson index, and Chao1 index, respectively, Fig. 1a). Moreover, despite a clear trend of decreased ICCs for all beta diversity indexes in the 4 antibiotics cohorts compared to the two no-intervention cohorts, the result was not statistically significant (Student *t* test, $p \geq 0.05$) except PCoA1 of Weighted Unifrac index and the average ICC value of PCoA1-5 of Unweighted Unifrac index. These results are probably due to the high variability observed between antibiotic types and personalized responses to each antibiotic. Nevertheless, the overall diversity ICC values of the cohort treated with a combination of meropenem, gentamicin, and vancomycin (A_MER-GEN-VAN) were extremely low with an average of 0.183, indicating a severe disturbance of the microbiome structure (Fig. 1a), while the ICC values of cohorts treated with cefprozil or cotrimoxazole were significantly higher than those of A_MER-GEN-VAN (paired *t*-test, adjusted $p < 0.1$) with an average of 0.453 and 0.368, respectively. On the contrary, the differences in the ICC values for beta diversity between no and lifestyle interventions were less obvious and again they were characterized by high variability among different types of intervention and of participants' responses in each study group (Fig. 1a).

By comparing the differences in the ICC values among the lifestyle intervention cohorts, we found that the I_MWP study, which used a multidisciplinary weight-loss program combining psychology, medicine, dietetics, and exercise, had average ICC values of 0.173 and 0.237, for alpha and beta diversity, respectively, significantly lower compared to all other single interventions (either dietetics or exercise) (paired *t*-test, adjusted $p < 0.1$). The comparisons among other cohorts in the lifestyle intervention category showed no significant differences (paired *t*-test, adjusted $p \geq 0.1$). We further compared the beta diversity ICC values of the I_MWP with the four antibiotic-treated cohorts and interestingly, we found that its impact on microbial stability was higher than the A_CEF and A_COT studies (paired *t*-test, adjusted $p < 0.1$).

In summary, we generally observed that the microbial stability estimated as ICCs of alpha and beta diversity is disturbed by antibiotics and lifestyle interventions, but the extent depends on the specifics of each environmental stressor. Furthermore, the insignificance of beta dissimilarity between interventions and no intervention, which may be due to the variability of responsiveness among individuals, supports the notion that generic approaches to altering the microbiome structure in an unbalanced state may not bring the desired structural changes. The baseline microbiome could potentially define the magnitude of the response of the community structure to external stimuli, something that we further explored below.

Fig. 1 ICC evaluation of taxonomic profiles among study cohorts. **a** ICC values of alpha and beta diversity indexes at the species level in each study cohort. The error bars represent 95% confidence intervals. Cohort type is indicated by blue, pink, and lilac colors for no intervention, antibiotic intervention, and lifestyle intervention, respectively. Only significant p values are shown (Student t test, $p < 0.05$). The red dash line indicates an ICC value of 0.5. **b** Circos plot showing the annotated species in our metagenomics datasets in a phylogenetic tree. In the inner circles, disease-related species are shown in light green (beneficial) and light orange (detrimental). Species ICC values are indicated in orange (ICC < 0.5), green (ICC \geq 0.5), and white (non-valid ICC). Barplots represent the median value of species abundance

Lifestyle interventions could have a comparable impact with antibiotics on individual species' stability

Looking at the ICCs of the 309 individual species annotated in our metagenomics dataset, we observed a clear stratification among the no-intervention cohorts and the other two study groups (Fig. 1b). In the no-intervention cohorts, 79.6% of the detected species were regarded as stable (mean ICCs > 0.5), while this percentage dropped to an average of 27.3 and 43.6% for antibiotics and lifestyle intervention cohorts, respectively. When looking into the individual studies, we observed a similar tendency for the species stability as for the community diversity. The ICCs of 99% of the species in the A_MER-GEN-VAN study were < 0.5 indicating that almost all bacteria present in the microbial community were affected. The percentage of species having ICCs < 0.5 was high for all antibiotics (78.4, 62.3, and 50.3% for A_CIP, A_COT, and A_CEF, respectively). Interestingly, three of the lifestyle interventions had a similar or even higher impact than the administration of single antibiotics on the stability of individual species. The I_MWP intervention resulted in the highest percentage of species with ICCs < 0.5, affecting 71.6% of the community members. The studies using a high-fiber diet (I_HFD) and a high-resistant starch diet (I_HRS) were also characterized by a high percentage of species with ICCs < 0.5 (68.6 and 61.1%, respectively).

Looking for global taxonomic patterns in the lifestyle intervention cohorts, the statistical comparisons among the major phylum showed that the ICCs of *Bacteroidetes* species were significantly higher compared to *Firmicutes* and *Proteobacteria* species (Student *t* test, $p < 0.05$). Using the lifestyle intervention cohorts, we also examined whether the stability of species is correlated with their relative abundance at baseline. However, only 16 out of 309 species showed a significant correlation (Spearman correlation, adjusted $p < 0.05$) between the ICC and relative abundance. By extracting information from the Disbiome Database, we were able to retrieve disease associations for 162 species annotated in our metagenomics datasets. The stability of 115 out of the 162 disease-associated species could be influenced by at least one of the lifestyle interventions. The I_HFD study resulted in ICC values < 0.5 for 83 species associated with a wide range of metabolic diseases (obesity, type 2 diabetes, and hypertension) confirming the potential of a high-fiber diet as a way to target dysbiotic microbiome states. Disease-associated species, whose stability was uniquely influenced by particular lifestyle interventions, were also found. The I_HFD showed specificity towards 12 disease-associated species, whereas I_LCD, I_MWP, and I_HRS showed specificity towards 8, 6, and 3 species, respectively (Table S2).

In order to perform a comparative analysis among all interventions, we extracted 65 species with valid ICCs (not NULL value of ICCs) in every individual study. Out of the 65 species, 47 were stable (ICCs > 0.5) in the no-intervention cohorts; however, all of them lost their highly stable status in at least one study of either antibiotic treatment or lifestyle intervention. Interestingly, among these 47 species, we found 5 species, *Bacteroides massiliensis*, *Bacteroides stercoris*, *Barnesiella intestinihominis*, *Parabacteroides merdae*, and *Parasutterella excrementihominis*, that remained stable in all the lifestyle interventions (ICCs > 0.5). These 5 species further showed resistance (ICCs > 0.5) to two of the antibiotic treatments, cefprozil (A_CEF) and cotrimoxazole (A_COT), suggesting that these species are highly stable. The aforementioned 5 species have a conditional effect on human metabolic diseases, playing either beneficial (non-alcoholic fatty liver disease, cirrhosis, multiple sclerosis, etc.) or detrimental (autism, Parkinson's disease, colon polyps, etc.) roles (Fig. 1b) [24]. We further explored the relative abundance of these 5 species across all samples and observed that they were all low-abundant species (< 0.92%), further confirming that stability and abundance are not correlated. *Alistipes indistinctus*, a species that has been associated with hypertension and autism, also showed an interesting stability pattern. *A. indistinctus* had a high prevalence of 32% but a low abundance of 0.25% on average. *A. indistinctus* showed high stability (ICC > 0.5) not only in the no-intervention cohorts but also in the cohorts with antibiotic treatments (except where the subjects were administered a cocktail dose of antibiotics, A_MER-GEN-VAN). Interestingly, a low-carbohydrate diet (I_LCD) and exercise (I_ETP) could result in an ICC < 0.5 for *A. indistinctus*, suggesting the potential of using specific lifestyle interventions to target highly stable and disease-associated species.

In summary, by evaluating the ICC value of each species across studies, we have identified both species that are highly resistant to any lifestyle and antibiotics intervention and species whose stability pattern can only be affected by specific lifestyle interventions. Interestingly, we also observed that lifestyle interventions can reach similar or even higher capability to impact the stability of microbial species as single antibiotics administration, questioning the broad characterization of antibiotics treatment as a more intense intervention compared to lifestyle interventions.

Identification of species associated with microbiome responsiveness

By calculating the day-to-day Bray-Curtis dissimilarities of each subject from the two longitudinal no-intervention

cohorts, we established the criteria to differentiate effective response to a microbiome-targeted intervention from normal fluctuation of the microbial community composition. We used the mean + SD (68% population) and mean + 2*SD (95% population) of the Bray–Curtis dissimilarity (see “Methods” for details) as the two cutoffs to distinguish individual responses and formed the following groups for downstream analysis: (i) non-responders (< mean + SD), (ii) partial-responders ([mean + SD, mean + 2SD]), and (iii) responders (> mean + 2SD) as shown in Fig. 2a. By evaluating the dissimilarity before and after intervention of each subject among the five lifestyle intervention cohorts, 47.3% of individuals were classified as responders, while 24.2% were partial-responders, and the remaining 28.5% were grouped as non-responders. We calculated the species ICCs before and after intervention in each study and compared them based on the responder classification. The species ICCs were significantly lower in the responders compared to the non-responders (paired *t* test, $p < 0.05$), confirming the grouping.

We subsequently used the baseline microbiome samples of each subject to perform a principal coordinates analysis (PCoA) based on the Bray–Curtis dissimilarities. The microbiome composition of the subjects grouped by the newly constructed classification from non-responder to responder was significantly different (PERMANOVA, $p < 0.05$, $R^2 = 0.05$, Fig. 2b). By comparing the species abundances between the non-responder, partial-responder, and responder groups, we found 41 species with significant differences among the groups (ordinal logistic regression, adjusted $p < 0.2$, Fig. 2c, Table S6). Interestingly, 37 out of the 41 species from the ordinal regression are highly stable species in the absence of interventions (ICCs > 0.5 in the no-intervention cohort), an important property for serving as biomarkers of community response. Among these 37 species, only 3 species were significantly enriched in the non-responder group, namely *Bacteroides stercoris*, *Prevotella copri*, and *Bacteroides vulgatus*. These 3 species remained significantly enriched in the non-responders group even when the lifestyle grouped subjects were combined with

non-responders, partial-responders, and responders from the antibiotics cohorts. Similarly, 17 out of the 37 species were found significantly enriched in the responders group even when combining the lifestyle with the antibiotics cohorts, including *Collinsella aerofaciens*, *Gordonibacter pamelaeeae*, *Ruthenibacterium lactatiformans*, *Turicibacter sanguini*, *Fusicatenibacter saccharivorans*, *Dorea longicatena*, and *Eubacterium hallii*, which were highly stable species (ICCs > 0.5).

Biosynthesis of amino acids and their taxonomic contributors as mediators of microbiome dynamic responses

Subsequently, we compared the MetaCyc pathway abundances among the three response groups using their baseline samples and found 116 pathways with significantly different abundances (Ordinal regression, adjusted $p < 0.1$), indicating a clear baseline stratification also at the functional level. Among the 116 pathways, enrichment of 34 was associated with non-responders and 82 with responders (Fig. S1). As observed with the species biomarkers of responsiveness, 97 out of the 116 pathways from the ordinal regression were highly stable in the absence of interventions (ICCs > 0.5 in the no-intervention cohort). We then investigated the contributions of the 41 significant species (Fig. 2c) to the 116 significant pathways using the stratified output of HUMAnN3. At least one of *B. stercoris*, *P. copri*, and *B. vulgatus*, the 3 species significantly enriched in non-responders, was taxonomically linked to 33 out of the 34 pathways enriched in non-responders, and all 3 species were contributing to the abundances of 24 pathways enriched in non-responders. Interestingly, when exploring the 82 pathways enriched in responders, we found only 4 pathways to have contributions from these non-responders associated species. Similarly, the 38 species enriched in responders were found to contribute to 51 out of the 82 pathways enriched in this response group.

In order to further investigate the relationship between species, pathways, and microbiome response, we performed Spearman correlation analysis between the 41 significant species and the 84 significant pathways that they contributed to (Fig. 3a). A consistent

(See figure on next page.)

Fig. 2 Microbiome compositional differences of responders, partial-responders, and non-responders to lifestyle interventions. **a** Bray–Curtis dissimilarity of longitudinal samples in subjects from no and lifestyle interventions. The two longitudinal no-intervention cohorts were combined in the first box. Bray–Curtis indexes dot colors indicate the microbiome response classification group by coral, blue, and green for non-responders, partial-responders, and responders, respectively. The two red dash lines represent the mean + SD and mean + 2*SD of the Bray–Curtis dissimilarities in the no-intervention cohorts as cutoffs to differentiate significant microbiome compositional changes from normal microbiome fluctuation. (CTL: study with no intervention; I_MWP: intervention study with multidisciplinary weight-loss program; I_LCD: intervention study with low-carbohydrate diet; I_HFD: intervention study with high-fiber diet; I_HRS: intervention study with high-resistant starch; I_ETP: intervention study with exercise training program). **b** Principal coordinate analysis of Bray–Curtis dissimilarity in non-responders, partial-responders, and responders to lifestyle interventions. **c** Relative abundances of the significant species using ordinal regression among non-responders, partial-responders, and responders groups ($p < 0.05$)

Fig. 2 (See legend on previous page.)

pattern between the 3 species enriched in non-responders and specific functional groups was not observed, besides the significant positive correlations (Spearman, adjusted $p < 0.1$) with fucufuranose biosynthesis, flavin

biosynthesis, and its precursors (Fig. 3a). On the contrary, a significantly larger and consistent pattern of positive associations between species and pathways was observed in the responders' enriched taxonomic and functional

signatures. Some of the strongest positive correlations were observed between the responders' enriched species, including *C. aerofaciens*, *F. saccharivorans*, *E. hallii*, *Gemmiger formicilis*, and *G. pamelaee*, and several pathways related to the biosynthesis of amino acids, e.g., arginine, isoleucine, and ornithine biosynthesis, among others (Fig. 3a). Metabolic cross-feeding of the aforementioned biosynthetically costly amino acids has been shown to promote stronger cooperative microbial interactions and drastically impact the community dynamics [25].

We subsequently performed differential abundance comparisons between responders and non-responders for the 2768 detected KEGG Orthology (KOs) and found 395 as significantly different (Wilcoxon rank sum test, adjusted $p < 0.1$). Among them, only 11 were more abundant in non-responders, whereas the remaining 384 KOs were highly abundant in responders (Fig. 3b). By mapping the significant KOs to the KEGG pathway database, the biosynthesis of secondary metabolites and biosynthesis of amino acids were two of the pathways with the highest KO contribution in responders, while very limited results were obtained for the non-responders (Fig. 3b). A significant enrichment of KOs related to the biosynthesis of amino acids in the responders compared to the non-responders was also observed (chi-square test, $p < 0.01$) with 43 KOs found to be significantly higher in responders, whereas none were higher in non-responders. Moreover, we investigated the species contributions to these amino acid-related KOs that were significantly enriched in the responders. We pinpointed 10 species that were top contributors to multiple significant KOs including *Faecalibacterium prausnitzii*, *Bacteroides cellulosilyticus*, *Fusicatenibacter saccharivorans*, *Eubacterium ramulus*, and *Eubacterium hallii* (Fig. 3c).

We subsequently built species co-abundance networks for responders and non-responders using the baseline samples, in order to further investigate the mechanisms by which responders' enriched species regulate microbial community structural changes. We explored two commonly used centrality measures that reflect the flow

of information in the network, the degree and closeness centrality. Responders have a more interconnected community network (Student t test, $P < 0.001$; Fig. 3d) and higher closeness centrality compared to non-responders (Student t test, $P < 0.001$; Fig. 3d). When the responder network was investigated in detail, we observed that 11 out of the 15 amino acid auxotroph (AAA) species identified recently in the study of Yu et al. [26] were present in the community network. These 11 AAA species had positive interactions with 30 species found from the ordinal regression to be highly abundant in responders (Fig. S2). Lastly, by integrating the species co-abundance network with the amino acid KO profile, we identified 6 significantly enriched species in responders (*C. symbiosum*, *B. cellulosilyticus*, *G. formicilis*, *F. saccharivorans*, *E. ramulus*, *D. longicatena*, and *E. hallii*) contributing to 22 amino acid-related KOs, which were further positively correlated with 6 AAA species (*R. gnavus*, *B. wadsworthia*, *B. adolescentis*, *D. formicigenerans*, *C. aerofaciens*, and *E. eligens*) (Fig. 3e).

In summary, our analysis revealed signature species in responders and non-responders that could serve as biomarkers of microbiome's resistance to lifestyle interventions. Furthermore, the functional capacity of enriched species in responders suggest that amino acid biosynthesis is playing an important role in regulating microbiome dynamics.

Development of a machine learning model to predict microbiome responsiveness

We then explored whether a machine learning (ML) model can be developed for predicting the degree of responsiveness of a microbiome community to lifestyle interventions. We used the abundance of bacterial species, genera, and pathways from the baseline samples among the cohorts with lifestyle intervention as features for training the model. We used the baseline samples of subjects classified above as responders ($N=78$) and non-responders ($N=47$, Table S8). We built a total of four different gradient boosting machine (gbm)

(See figure on next page.)

Fig. 3 Microbiome functional differences of responders, partial-responders, and non-responders to lifestyle interventions. **a** Heatmap showing Spearman's rank-based correlations between species and pathways with significantly different abundance (using ordinal regression among non-responders, partial-responders, and responders groups; adjusted $p < 0.1$). Only pathways with contributions from at least one of the species enriched in the same condition are shown. FDR-corrected $p < 0.1$ was deemed significant. The condition where the species or pathways are enriched is shown in coral and green for non-responders and responders, respectively. **b** Barplots showing the number of significant KOs mapped to each enriched pathway in responder and non-responder in green and coral, respectively. **c** Volcano plot of differentially abundant KOs based on the comparison between responders and non-responders. The \log_2 fold change and the $\log_{10} p$ values adjusted for multiple testing are plotted for each of the KOs. The dots marked with green represent significant KOs and the dots marked with red represent significant KOs involved in the biosynthesis of amino acids. The significant species which contributed to these KOs were annotated in the plot. **d** Comparison of the degree and closeness centrality between responders (R) and non-responders (NR) SparCC networks (Student t test, ***: $p < 0.001$). **e** Co-abundance network among species enriched in responders, the amino acid-related KOs, and amino acids (AA) auxotroph species (only significant correlations are considered, $p < 0.05$). Color intensity of the edges refers to the correlation value. The green, blue, and red color of the nodes represents species enriched in responders, the amino acid-related KOs, and AA auxotroph species, respectively

Fig. 3 (See legend on previous page.)

models depending on the input data to classify patients as responders or non-responders: a species, a genus, a taxonomic (with genus and species), and a hybrid model using pathways and taxa (Table S3).

We found that the species-based model classified the responders vs non-responders correctly, with an AUC of 0.75 ± 0.10 . Eight species were selected in more than 70% of the 100 gbm species-based models, and *P. copri* (a significantly enriched species in non-responders) was selected in all the models. The classification performance was slightly increased in the genus-based model with an AUC of 0.79 ± 0.09 . In the case of the genus-based model, 16 genera were consistently selected (>70% of the 100 gbm models), and 2 were selected in all the models (*Bacteroides* and *Prevotella*). Similar classification performance was obtained when combining species and genus together (0.78 ± 0.08 AUC) or combining species with pathways (AUC of 0.74 ± 0.10). We built a final taxonomic-based model (see “Methods” for details) and obtained an AUC of 0.81 for the training set (sensitivity = 0.81 and specificity = 0.78, Fig. 4a). Recursive feature elimination was performed to reduce the dimensionality

of the dataset to select the most important taxa for the classification of the responsiveness of the microbiome community. Figure 4b shows the feature importance of each of the selected features, or in other words, a score that measures how powerful is each feature in classifying the microbiome responsiveness. The final model consisted of 18 species and 12 genera as the top features, including 13 species and 6 genera that were significantly associated with responsiveness in the ordinal regression analysis (Fig. 4B, Table S4). The final model was then validated in two different external cohorts. The first cohort of subjects with inflammatory bowel disease (IBD) underwent an IBD-anti-inflammatory diet (IBD-AID, consumption of prebiotics, probiotics, and beneficial foods) for a period of 8 weeks, and the second cohort underwent a whole grain-rich diet (WGD) intervention for 8 weeks and consisted of overweight subjects. A total of 6 responders and 6 non-responders were identified in the IBD cohort, and 14 responders and 25 non-responders in the overweight cohort based on the same criteria established. The predictive power of the model in the external cohorts remained high with an AUC of 0.86

Fig. 4 Performance of the machine learning model to classify individuals as responders and non-responders based on the degree of microbiome response. **a** Receiver operating characteristic curves (ROC) for the final model and external validation. Confusion matrix of the training model and external validation cohorts. IBD-AID: Inflammatory bowel disease-anti-inflammatory diet; WGD: whole grain diet. **b** Variance importance of the top 20 features selected by the final model. Significantly different in abundance species using ordinal regression are marked with *. The importance score of each feature is indicated inside the blue circles

(sensitivity=0.83 and specificity=0.83) for the IBD-AID intervention and an AUC of 0.73 (sensitivity=0.79 and specificity=0.68) for the WGD intervention (Fig. 4A).

In summary, a gradient boosting model based on taxonomic data was developed achieving a good prediction of the microbiome response in two external cohorts including individuals from different ethnic backgrounds with metabolic and non-metabolic diseases that underwent lifestyle interventions.

Discussion

From metabolic to immune to neurological disorders, the microbiome influences the development, progression, and therapeutic outcomes of diseases [27–30]. A novel treatment approach for both disease control and disease prevention involves altering host–microbiota interactions through tailored lifestyle interventions. Unlike antibiotics usage, which is broadly reported to have a negative impact on healthy host by significantly decreasing the overall gut microbiome diversity, lifestyle interventions are regarded as a beneficial strategy to improve the metabolic performance by modulating the host-gut microbiome. Changes in the composition of the bacterial consortia in the gut from a disease-associated to a more homeostatic state are one of the desired effects of lifestyle interventions. Furthermore, comparing with the dramatical dysregulation of gut microbiome after receiving high doses of antibiotics [15], although the response to lifestyle interventions may have a common signature within the population, heterogeneous and highly personalized shifts in the human microbiota have been confirmed in several studies [31–35].

Here we attempted to identify robust and generalizable biomarkers among the gut microbial communities associated with the degree of change in the microbiome structure. We performed longitudinal shotgun metagenomics analysis from a wide range of lifestyle interventions, and established criteria to classify individuals as responders and non-responders based on their gut microbiome restructuring, using as a point of departure the natural fluctuation of a healthy gut microbiome without any intervention. We identified *P. copri*, *B. stercoris*, and *B. vulgatus* to be highly abundant in the baseline microbiomes of individuals in whom lifestyle interventions had only a minor impact on the microbial community's structure. Similarly, we found these 3 species enriched in the microbiome of individuals that were resistant to antibiotics treatment in line with recent evidence [36] from a 16S rRNA-based analysis in which the response to antibiotics in humans is determined by specific genera in the pre-treatment microbiota. Interestingly, *P. copri*, *B. stercoris*, and *B. vulgatus* are highly stable in the absence of

interventions (ICCs>0.5) suggesting their potential as biomarkers for microbiome stratification.

In contrast to the low number of species found enriched in the resistant microbiomes, we found 38 species to be highly abundant in the microbiomes that were significantly re-structured in response to lifestyle interventions. Interestingly, almost all species enriched in responders were positively correlated with at least one amino acid biosynthesis pathway. The interchange of vital metabolites, also known as metabolic cross-feeding, is a crucial process that controls the development and composition of microbial communities. Case-by-case explanations of the significance of amino acids in natural interkingdom and interspecies exchange networks have been provided by entomological investigations [37, 38]. Furthermore, a considerable proportion of all bacteria, according to comparative analysis of microbial genomes, lack crucial pathways for amino acid production [39]. Therefore, amino acid auxotrophy may promote cooperative interactions between different bacteria in the microbiome [25]. Our findings here suggest that microbiomes with a high abundance of amino acid biosynthesis pathways are also more likely to respond to different lifestyle interventions including both dietary and exercise interventions, targeting the restructuring of gut microbial communities. This finding is consistent with previous studies that amino acid biosynthesis is enriched in elite athletes [40] and decreased with high-fat diet treatment [41], highlighting the inner correlation between exercise and diet interventions. Therefore, supplementation with *F. prausnitzii*, *F. saccharivorans*, *E. ramulus*, and *E. hallii*, or other species both enriched and identified here as major taxonomic drivers of amino acid biosynthesis in the responder group, should be explored as a way to restore the metabolic flexibility required prior to microbiome-targeted lifestyle interventions. Importantly, among these potentially beneficial species, *F. prausnitzii*, *F. saccharivorans*, and *E. hallii* were reported to be enriched after exercise and diet intervention across multiple studies [42–47].

Similar to personalized medicine, personalized lifestyle approaches look for critical microbiome characteristics that can predict how an individual will react to specific lifestyle components. This information can then be used to help design a lifestyle that will have positive effects. Identifying the interactions between the host, the microbiome, and lifestyle exposures that influence lifestyle responses is the fundamental difficulty in realizing the potential of a microbiome-informed customized lifestyle. Whereas previous studies have demonstrated that the microbiome composition can be used to classify individuals into responders and non-responders on the basis

of the health improvements from lifestyle interventions [48, 49], predictive models of personalized microbiota response have not yet been developed. We demonstrated here that it is possible to develop a generic ML model covering diverse lifestyle exposures that predicts the scale of microbiome change using only the baseline microbiome composition. Our model, which achieved AUCs up to 0.86 in external validation cohorts, can potentially be used for individual microbiome-based stratification, as an intermediate step towards personalized recommendations for improving the success rates of certain lifestyle interventions.

Our study has limitations. Even though several comparative analyses among studies have been performed using the ICC values [22], it is possible that ICCs may be affected by the general setup of each study, including the storage and sampling procedures, which may influence the outcome of the comparative analysis. Nevertheless, previous studies suggested a relatively stable bacterial community evaluated by ICCs with limited impact by the processing speed and storage duration [50, 51]. Furthermore, DNA extraction methods have been shown to influence the microbiome community results [52], and remained inconsistent across different cohorts in our study. Nevertheless, the impact of DNA extraction methods on metagenomic shotgun sequencing analysis of stool samples was reported to be the lowest compared to other tissue [53]. Lastly, following a strict filtering criterion, only two large-scale studies, both with Caucasian subjects, were selected to represent the healthy gut microbiome with high confidence of disease absence. Analysis of a larger cohort, well-balanced in gender and ethnicity, would allow to establish a more generalized baseline of microbiome variation in healthy individuals. The number of studies with dense longitudinal characterization of the microbiome upon lifestyle interventions is also limited and in most cases the clinical and biochemical data of the subjects are not available. Larger, more complete, and balanced datasets would allow to increase the statistical power of the data analysis and use of advanced algorithms, like deep learning, to investigate the correlation between microbiome and host response to lifestyle interventions. Nevertheless, our study offered novel insight into the microbial species and functions that may determine microbiome dynamics in response to lifestyle interventions.

Conclusions

Human gut microbiome serves as a therapeutic target for multiple diseases through lifestyle interventions. However, subjects may have different treatment efficacy which may be due to the response of gut microbiota towards the interventions. In this study, we observe individuals

with either highly plastic or resistant microbial composition with the stress of lifestyle interventions. We further identify key species and functions such as *Bacteroides stercoris*, *Prevotella copri*, and amino acid biosynthesis regulating the responsiveness of the gut microbiota. Last but not least, we demonstrate with our machine learning model that it is possible to predict microbiome resistance to change in response to lifestyle interventions using the baseline microbiome composition. In summary, this study shows that the composition and function of the gut microbiome are important to determine their response to lifestyle interventions and this knowledge may help to improve the design of personalized lifestyle approaches.

Methods

Data collection and availability

In this study, we collected shotgun metagenomic sequencing data from 10 publicly open available microbiome projects. These projects included (i) 2 longitudinal cohorts of healthy subjects ($N=231$); (ii) 4 antibiotic intervention cohorts ($N=71$); and (iii) 5 lifestyle intervention cohorts ($N=165$) with metabolically diseased subjects that underwent dietary and/or exercise interventions (Table 1 and Table S5). The 2 longitudinal studies of healthy subjects with no intervention applied, abbreviated as CTL_1 and CTL_2, respectively, served as controls of normal gut microbiota fluctuation. In both studies, the selected subjects were not asked to follow diet or lifestyle recommendations and they followed their own lifestyle habits. From CTL_1, two pairs of samples taken 6 months apart from 140 subjects were used. In CTL_2, we used data from 78 subjects with one pair of samples and 4 subjects with a dense long-term time series. We used pair samples with a time interval between pairs of 2–3 months. We also selected samples that were taken 4 days apart (12 such pair samples were included). For the antibiotic intervention cohorts, the study of Palleja et al. [15] provides a cohort of healthy subjects that underwent a 4-day intervention with a cocktail of 3 last-resort antibiotics: meropenem, gentamicin, and vancomycin (A_MER–GEN–VAN). The Raymond et al. [54] cohort is composed of healthy participants that were treated twice a day with an oral dose of cefprozil for 7 days (A_CEF). The Willmann et al. [17] study provides two different cohorts of hematological patients receiving prophylactic antibiotics during a mean period of 6 days. One cohort was treated with ciprofloxacin (A_CIP) and the other with cotrimoxazole (A_COT). Regarding the lifestyle intervention cohorts, the first cohort was obtained from the study of Louis et al. [18] in which obese patients were involved in a multidisciplinary weight-loss program for 3 months (I_MWP). In Mardinoglu et al. [19], Non-alcoholic fatty liver disease (NAFLD)

obese subjects underwent a low-carbohydrate diet with increased protein content during a 2-week period (I_LCD). The cohort of Zhao et al. [20] is composed of participants diagnosed with type 2 diabetes (T2D) that were administered a high-fiber diet for 3 months (I_HFD). The Ni et al. study provides data from NAFLD patients that were involved in a diet with high-resistant starch type II content for 4 months (I_HRS). The last cohort, from Liu et al. [9], is composed of prediabetes patients that enrolled in an exercise training program 3 days/week for a period of 3 months (I_ETP). More information and the number of samples used in each cohort are shown in Table 1 and Table S5. The Olendzki et al. [11] cohort was used as external validation of the machine learning predictive final model of response to lifestyle interventions. It is an IBD-anti-inflammatory dietary intervention (IBD-AID) for 8 weeks in a total of 15 subjects with inflammatory bowel disease. A second external validation cohort from Nielsen et al. [55] composed of 50 overweight subjects that underwent a whole grain dietary intervention for 8 weeks was used.

Quality control and taxonomic profiling

For the quality control of the raw reads, human DNA contaminations were removed using *bwa mem* against the human reference genome *ucsc.hg19*, and adaptors, low-quality reads, bases, or PCR duplicates were filtered as previously described [56]. The high-quality reads were taxonomically profiled at different taxonomic levels using *MetaPhlAn 3.0* [57]. Default settings were used to generate taxonomic relative abundances (total sum scaling normalization).

Functional profiling

Microbial gene family abundances in metagenomic DNA reads were estimated using *HUMAnN 3.0* [58]. Gene families were further mapped to the *MetaCyc* metabolic pathway database included in *HUMAnN3* to obtain the *MetaCyc* pathway abundances. KOs with the species contribution were obtained in *HUMAnN3* by *KEGG* database. Tables of pathway and gene family abundance obtained using *HUMAnN3* were normalized to copies per million (CPM), including unmapped and unintegrated read mass.

Microbiome diversity measurements

Microbiome diversity was calculated based on the species, phylum, and KO gene abundance profiles, respectively. For taxonomic diversity, 3 alpha diversity indexes (including Shannon diversity, Simpson diversity, Chao1 diversity) and 3 beta diversity indexes (including Bray–Curtis dissimilarity, Weighted and Unweighted UniFrac distance) were analyzed by the *vegan* package [59] and

phyloseq package [60] in R, respectively. For functional diversity, the 3 mentioned alpha diversity indexes and Bray–Curtis dissimilarity were calculated. Principal coordinate analysis (PCoA) based on the beta diversity was performed, and the top 5 axes were included for follow-up analyses.

ICCs of microbiome measurements

The intraclass correlation coefficient (ICC) that ranges from 0 to 1 was used to represent the microbial stability (and resistance to perturbations) from totally unstable (ICC=0) to perfectly stable (ICC=1). We evaluated the ICC value for each diversity measurement described above and for the species, genus and *MetaCyc* pathway profiles using relative abundances to investigate the microbial stability within individuals of the no-intervention cohort and the resistance to perturbations within individuals from intervention cohorts. Diversity indexes were transformed into Gaussian distribution with *bestNormalize* package in R and the arcsine square-root transformation was implemented to the relative abundances of taxonomic and functional profiles as proposed previously [61]. After the metric transformation, ICC estimates and their 95% confident intervals were calculated using the *rptR* [62] package in R based on a mean-rating, absolute-agreement, 2-way random-effects model with 1000 bootstraps. The statistical comparisons of ICC values among cohort types were performed with Student *t* test. False discovery rate (FDR) correction was implemented to adjust *p* value for multiple comparisons.

Defining degree of response to perturbation

We first calculated the Bray–Curtis dissimilarity of the microbiome composition between samples within 1–2 days for each individual from the longitudinal cohorts with no intervention, which we used to estimate the daily fluctuation of the microbiome without disturbance. We then evaluated the degree of response towards lifestyle (and antibiotic) interventions of each subject by calculating the Bray–Curtis dissimilarity between baseline and each time point after the intervention and selected the time point with the first peak value of Bray–Curtis distance to baseline. The information of the selected time point for each subject among studies are shown in Table S7. The mean + SD and the mean + 2SD of the Bray–Curtis dissimilarity calculated from the control cohorts (no-intervention) were further used as the two cut-offs in the lifestyle interventions for distinguishing between responders (> mean + 2SD), partial-responders ([mean + SD, mean + 2SD]) and non-responders (< mean + SD). PERMANOVA tests were performed among responders, partial-responders, and non-responders of the lifestyle interventions using the

Bray–Curtis dissimilarity of baseline microbiome, and an ordinal regression model was used to find statistically significant taxonomic and functional differences among the three groups by applying the ordinal package in R. FDR correction was implemented to adjust p value for multiple comparisons.

Network analysis

In order to investigate the differences and the role of specific taxa in the microbiome community between the subjects with different responses, network analyses were performed using taxonomic data of the baseline samples. To build SparCC correlation networks for the responder and non-responder subjects, FastSpar R package was used. Only significant correlations between species were considered (adjusted $p < 0.1$). Cytoscape version 3.9.0 [63] was used to analyze the networks. Statistical comparisons between the degree and closeness centrality of the taxonomic networks of responders and non-responders were performed using the *t.test* function from R package stats. Furthermore, the Spearman correlation among species significantly enriched in responders, their contributed KOs which were related to the biosynthesis of amino acid and AA auxotroph species were performed in R. Only significant correlations were considered (adjusted $p < 0.1$).

Development of machine learning models

The Caret [64] R package was used to build a gradient boosting machine (gbm) model to train and classify responders and non-responders based on the baseline microbiome. We built 4 different models depending on the input data provided: a species model, a genus model, a taxonomic model using species and genus data, and a hybrid model using species, genus, and pathways data. To obtain a learning model with good interpretability and generalizability, we built a final model that included not only internal validation but also external validations, as it is critical to developing quality machine learning models [65]. The following approach was applied to build the model which included the following steps: (1) loaded the specific data (depending on the model species, genera, or pathways); (2) used the *createdatapartition* function from caret package to select 80% of the samples as training set; (3) performed feature selection in the training set selecting the top 30 features by applying recursive feature elimination using the *rfe* R function; (4) trained the model after centering, scaling the data, and removing variables with near-zero variance, using leave-one-out cross-validation (LOOCV) as a resampling method. Leave-one-out cross-validation (LOOCV) is a special case of K -fold cross-validation, where K equals the number of observations in the dataset [66]. Cross-validation techniques are used for evaluating ML models protecting

the model against overfitting or selection bias and giving insights on how the model will generalize when an independent dataset is provided to the model. GBM was used as a machine learning model method and grid search to tune the hyperparameters. “Interaction.depth”, “n.trees”, “shrinkage”, and “n.minobsinnode” were applied by the *expand.grid* R function; (5) tested the training model in the 20% of the data. Doing only one partition may provide biased results depending on the data split (“lucky” or “unlucky” split) [67]. Therefore, in order to perform a robust interpretation of the model’s performance, the machine learning algorithm was applied 100 times using different random training-test splits; (6) steps 2–5 were repeated 99 times to obtain the overall testing performances. Model performance was assessed using the *evalm* function from Mlevel R package, and receiver operating characteristic curve (ROC) was obtained using the R package *pROC*; (7) then applied steps 3–4 to the entire dataset to obtain the final machine learning model; (8) evaluated the model’s performance in external cohorts (information about the external cohorts is found in the “Supplementary Information” section).

Data visualization

The circo plot was made using iTOL (interactive Tree of Life) v6 [68]. Network visualizations were made by using the software Cytoscape version 3.9.0 [63]. All the other figures were generated by R software 3.6.3, using *ggplot2*, *ggcorrplot*, and *pROC* packages.

Manuscript III

Genetic variation in IL-17A regulation and mycobiome dysbiosis contribute to non-alcoholic fatty liver disease

Nadja Thielemann^{1,†}, Sara Leal Siliceo^{2,†}, Monika Rau³, Michaela Herz¹, Natalie E. Nieuwenhuizen¹, Alexander Maximilian Aldejohann¹, Heike M. Overview

In manuscript III, we aimed to investigate how intestinal fungi contribute to NAFLD development by looking into a possible antifungal immunity and a potential mycobiome dysbiosis. Therefore, we characterized the fecal mycobiome of a NAFLD cohort to elucidate if potential alterations in Th-17 (T-helper cells that produce interleukin-17) signaling are accompanied by mycobiome dysbiosis. In addition, we further investigated how the combination of genetic variation in Th-17 signaling and mycobiome dysbiosis contributes to inflammation in steatohepatitis (NASH). These results showed that NAFLD patients harboring a genetic variation in their IL-17A gene concomitantly present increased levels of *Candida* CTG species, and these factors predispose to develop disease progression up to NASH and advanced fibrosis.

32 **ABSTRACT**

33 Non-alcoholic fatty liver disease (NAFLD) is the leading cause of chronic liver disease in
34 Western countries. In non-alcoholic steatohepatitis (NASH), fat accumulation triggers
35 inflammatory processes with a central role of Th17 responses. We show that the *IL-17A*
36 rs2275913 minor allele variant is associated with fibrosis progression in NAFLD patients,
37 indicating a genetic pre-disposition to NASH-associated inflammatory processes. Fungal
38 gut commensals including *Candida albicans* are potent activators of Th17 responses. To
39 investigate if alterations in Th17 signaling are accompanied by mycobiome dysbiosis, we
40 characterized the fecal mycobiome in our NAFLD cohort. In NAFLD patients with
41 advanced fibrosis, we observed an increased abundance of *Candida* CTG-clade species. In
42 addition, T cells from donors carrying the minor allele variant secreted significantly higher
43 IL-17A levels in response to stimulation with *Candida* CTG-clade species. This
44 combination of increased IL-17A release and mycobiome dysbiosis may thus result in
45 enhanced inflammation, revealing a significant role of intestinal fungi in NAFLD.

46
47 **Keywords:** Mycobiome, Intestinal Fungi, Th17 Signaling, IL-17A, NAFLD, NASH,
48 *Candida*, liver fibrosis, liver inflammation

49
50 **MAIN**

51 Non-alcoholic fatty liver disease (NAFLD) has emerged as the major cause of chronic liver
52 disease in recent years, reaching a global prevalence of around 25%¹. The accumulation of
53 excess fat in the liver in the absence of relevant alcohol consumption is functionally linked
54 to obesity and risk factors like type 2 diabetes and metabolic syndrome². Fat accumulation
55 in hepatocytes is the main driver of NAFLD pathogenesis and constitutes a non-alcoholic
56 fatty liver (NAFL)³. Ongoing fat accumulation and emerging lipotoxicity trigger the onset
57 of inflammation, characterizing non-alcoholic steatohepatitis (NASH). Inflammatory
58 processes eventually lead to the development of fibrosis which could ultimately result in a
59 cirrhotic liver⁴. It is unclear why some patients progress to NASH and others do not, but
60 there is some indication that Th17 responses are associated with progression to NASH⁵⁻⁷.

61 The liver receives approximately 75% of its blood supply via the portal vein and is
62 thus closely connected to the human intestinal tract, which is massively colonized by
63 microorganisms – bacteria, viruses, fungi – collectively known as the microbiome⁸.
64 Importantly, gut microbiota dysbiosis has been repeatedly observed in obesity and type 2
65 diabetes mellitus^{9,10} and recent data provide clear evidence that the composition of gut
66 microbiota also has a direct impact on the pathogenesis of NAFLD¹¹⁻¹⁴. A previous study
67 characterized a significantly higher abundance of short chain fatty acid (SCFA)-producing
68 bacteria such as *Fusobacteriaceae*, *Prevotellaceae*, and *Ruminococcaceae* in the gut of
69 patients with advanced NAFLD¹⁵. In contrast to the gut bacteriome, the composition of
70 intestinal fungi is less well characterized and mycobiome studies are hampered by non-
71 standardized protocols, technical difficulties and incomplete reference databases^{16,17}.
72 Although no “core gut mycobiome” has been defined so far, some species like *Candida*
73 *albicans* have been identified as key colonizers and are known for their multiple
74 interactions with the human host in health and disease^{18,19}. Recent work identified *C.*
75 *albicans* as the major direct inducer of human antifungal Th17 cell responses²⁰. Recognition
76 of fungal β -1,3-glucan by dectin-1 receptors can promote Th17 signaling²¹. Downstream
77 signaling of this pattern recognition receptor involves the formation of a complex of
78 CARD9, Bcl10 & MALT1, which ultimately leads to Th17 cell differentiation and IL-17
79 secretion²². Thus, immune activation induced by this single component of the mycobiome
80 could be a central mechanism for systemic induction of human Th17 responses that have a
81 broad impact upon the human body²⁰. Recently, Demir et al. characterized a distinct fecal

82 mycobiome signature in non-obese NAFLD patients to be associated with liver disease
83 severity. The abundance of e.g. *Malassezia* sp. was increased in NAFL patients, whereas
84 *C. albicans* and *Penicillium* spp. abundance were increased in NASH patients. Increased
85 intestinal *C. albicans* numbers were mirrored by increased levels of systemic antibodies
86 against *C. albicans* in NAFLD patients with advanced fibrosis²³. Interestingly, intestinal *C.*
87 *albicans* has also been linked to the pathogenesis of alcoholic liver disease via its exotoxin
88 candidalysin^{24,25}. In both cases however, a link between Th17 activation and intestinal fungi
89 has not been addressed.

90 The aim of our study was to clarify how associations between genetic variations in
91 antifungal immunity and the resident intestinal mycobiome contribute to NAFLD
92 pathogenesis. We have identified a novel risk variant in *IL-17A* and show that intestinal
93 colonization with *C. albicans* and related species (*Candida* CTG-clade) might contribute to
94 enhanced inflammation in the presence of this risk genotype.

96 RESULTS

97 Study population

98 A total of 482 European subjects were recruited for this study including 230 histology-
99 proven NAFLD patients (89 NAFL and 141 NASH). Figure 1 illustrates the clinical and
100 histological phenotypes of the study participants in a flow diagram. Stool samples were
101 collected from a sub-cohort of subjects (42 NAFL, 79 NASH, 100 NAFLD). Due to the
102 high frequency and often diverse nature of NAFLD we mainly aimed for comparisons
103 within the disease group. However, as an additional control a group of healthy individuals
104 (HC) was included. Patients with 6 months antibiotic-free intervals were analyzed
105 separately.

107 Genetic variation in IL-17A predisposes patients to develop fibrotic NAFLD

108 Th17 responses and IL-17A signaling have been shown to be an important part of
109 inflammatory activation in NASH⁷. In an extensive dbSNP database search for genetic
110 variants in Th17 signaling associated genes linked to gastrointestinal disease with
111 inflammatory properties, we identified the rs2275913 *IL-17A* SNP as one suitable
112 candidate²⁶. TaqMan SNP genotyping of our 451-patient NAFLD cohort identified 175 G/G
113 (homozygous for major allele variant, 38.8%), 55 A/A (homozygous for minor allele
114 variant, 12.2%), and 221 A/G (heterozygous, 49%) genotypes (Fig. 2a). Thus, genotype
115 frequencies are in Hardy-Weinberg equilibrium and selection for specific genotypes was
116 excluded (Extended Data Fig. 1). The calculated minor allele frequency (MAF) of 36.7%
117 was just slightly elevated in comparison to the published ALFA European cohort MAF of
118 34.85%. Statistical analysis of genotyping data revealed an association between the *IL-17A*
119 rs2275913 genotype and fibroscan liver stiffness values ($P_{\text{Kruskal-Wallis}}=0.368$; $P_{\text{glm}}=0.029$;
120 GLM adjusted; Fig. 2c). Patients carrying the SNPs minor allele variant (A/A & A/G) had
121 more severe fibrosis than homozygous major allele variant carriers (G/G; $P_{\text{glm}}=0.0292$,
122 GLM adjusted). Due to its potential as a major genetic risk factor for NAFLD²⁷, we
123 validated the association of available *PNPLA3* rs738409 genotyping data from a previous
124 study²⁸ to fibroscan stiffness values of patients in this cohort ($P_{\text{Kruskal-Wallis}}=0.105$;
125 $P_{\text{glm}}=0.028$; GLM adjusted; Fig. 2b) and adjusted all SNP-based generalized linear model
126 (glm) calculations for the *PNPLA3* rs738409 risk genotype. We also analyzed the
127 rs16910526 SNP in the *CLEC7A* gene (coding for Dectin-1) and the rs4077515 SNP in the
128 *CARD9* gene, both also related to Th17 response, but did not find an association with
129 NAFLD disease parameters (Extended Data Fig. 2).

131 **Alpha diversity of patients with NASH, but not NAFL, is affected by prior use of**
132 **antibiotics**

133 Intestinal colonization by *Candida* is a major inducer of Th17 responses²⁰. Thus, we built
134 ITS1 libraries for 145 subjects from our study cohort to estimate the fungal genus and
135 species abundance and explore the possible role of fungi in NAFLD progression and liver
136 damage. On average, we generated 15,500 high-quality, non-chimeric reads per sample
137 while fungal annotation identified 29 genera and 223 species in total. Investigating genus-
138 level fungal profiles showed that *Saccharomyces*, *Penicillium*, and *Candida* CTG-clade
139 were the top most abundant fungi among our study participants, at 16.7%, 16.1%, and
140 12.5%, respectively. We used the *Candida* CTG-clade for genus clustering as *Candida* is a
141 polyphyletic genus comprising a large variety of phylogenetically distant species. To
142 account for this, we clustered only *Candida spp.* characterized by an alternative decoding
143 of the CTG codon leading to a serine amino acid instead of leucine²⁹. Members of the CTG-
144 clade are pathogenic *C. albicans*, *Candida tropicalis*, *Candida dubliniensis*, *Candida*
145 *parapsilosis* and non-pathogenic *D. hansenii*. Although still commonly referred to as
146 *Candida*, other species are only distantly related to *Candida* CTG. Important examples
147 include *Candida glabrata*, *Kluyveromyces marxianus* (formerly *Candida kefyi*) and *Pichia*
148 *kudriavzevii* (formerly *Candida krusei*)^{29,30}.

149 In total, 76 NAFL, NASH, and NAFLD subjects in our cohort reported antibiotic
150 use 6 months before the stool collection. A recent study showed that antibiotics might have
151 a longterm influence on the human gut mycobiome³¹. Therefore, we investigated whether
152 antibiotics had a noticeable impact on the mycobiome profiles of the different disease
153 groups. We found that the mycobiome alpha-diversity measured by the Shannon and
154 Simpson index at genus level was significantly increased in NASH subjects who used
155 antibiotics compared to the antibiotic-free subjects (Wilcoxon rank-sum test, P=0.028 and
156 P=0.025, Shannon and Simpson respectively; Extended Data Fig. 3). However, no
157 differences were found in the NAFL and NAFLD groups between antibiotic and antibiotic-
158 free subjects. Using Aitchison distance to compute beta-diversity, no differences were
159 found between the antibiotic and antibiotic-free subjects in any of the disease groups
160 (PERMANOVA adjusted for age, gender and obesity-related parameters, P>0.05).
161 Nevertheless, to avoid a possible impact of antibiotics on the downstream analysis, two
162 approaches were used for the mycobiome comparisons. For all the main results, unless
163 specified, a dataset with only the long-term antibiotic-free samples was used. Alternatively,
164 mycobiome analysis was performed using all samples, adjusting for antibiotic intake when
165 appropriate (see Methods for details).

166
167 **A distinct mycobiome structure characterizes NASH patients**

168 To study the mycobiome changes related to NAFLD progression, we first performed
169 pairwise comparisons between NAFL, NASH, NAFLD and HC in alpha diversity measured
170 by the Shannon and Simpson index and we found no significant differences between the
171 four diagnosed groups (Wilcoxon rank-sum test, P>0.05 for all pair group comparisons for
172 Shannon and Simpson index). Beta diversity analysis using Aitchison distance to assess the
173 overall mycobiome community differences showed that the fungal composition was
174 significantly different between NASH and HC subjects (PERMANOVA adjusted for age,
175 gender and obesity-related parameters, P=0.01, Fig. 3a), but no significant differences were
176 found in any other pairwise comparison (PERMANOVA adjusted, P>0.05).

177 We then explored the fungal abundance differences between the diseased groups
178 (NAFL, N=31; NASH, N=64; NAFLD, N=50) and healthy controls (HC, N=25). Again,
179 fungi were grouped according to genus, except for the *Candida* CTG clade. The most
180 abundant genus in the HC group was *Penicillium* (22.2%), followed by *Saccharomyces*

181 (20.9%), and the *Candida* CTG-clade (12.2%) (Fig. 3b) and a similar abundance pattern
182 was observed for the NAFL and NAFLD groups (Fig. 3b). However, in NASH, the most
183 abundant genus was the *Candida* CTG-clade (17.8%), followed by *Saccharomyces* (14.1%)
184 and *Penicillium* (12.5%) (Fig. 3b). From the most abundant genera, we found
185 *Saccharomyces* significantly decreased in abundance in NAFL and NASH in comparison
186 to HC (Wilcoxon rank-sum test, $P_{HCvsNAFL}=0.026$, $P_{HCvsNASH}=0.027$, Fig. 3c). *Penicillium*
187 was also found significantly decreased in abundance in all disease stages in comparison to
188 HC even though it did not reach statistical significance in comparison to NAFL (Wilcoxon
189 rank-sum test, $P_{HCvsNASH}=0.038$, $P_{HCvsNAFLD}=0.023$, $P_{HCvsNAFL}=0.051$, Fig. 3c). However,
190 the statistical significance was lost for both genera when accounting for age, gender, and
191 obesity-related parameters (Generalized Linear Model (GLM) adjusted, $P>0.05$, Fig. 3c),
192 suggesting a potential confounding effect in the abundances of the two genera by these
193 factors.

194 We subsequently repeated all the analytical steps using the full cohort and not only
195 the antibiotics-free subjects and confirmed the significant differences in beta diversity
196 between the NASH and HC groups (PERMANOVA adjusted, $P=0.034$, Extended Data Fig.
197 4a) and the significant decrease in abundance of *Penicillium* in the NAFLD and NASH
198 groups compared to HC ($P_{HCvsNASH}=0.03$, $P_{HCvsNAFLD}=0.02$, Wilcoxon rank-sum test;
199 $P_{HCvsNASH}=0.007$, $P_{HCvsNAFLD}=0.42$, GLM adjusted). Even though it did not reach statistical
200 significance as it did when using the antibiotic-free set of samples, the same trend was
201 observed for *Saccharomyces*, having lower abundance in the NASH and NAFLD groups
202 compared to HC (Wilcoxon rank-sum test, $P_{HCvsNASH}$ and $P_{HCvsNAFLD} < 0.1$).

203 We then used 16S data from our cohort in order to build a microbial community
204 network to identify possible associations between fungal and bacterial genera and NAFLD
205 progression. Using all cohort samples, we built a community network using FastSpar³², and
206 identified a total of 5,848 significant correlations (SparCC, $P<0.05$) from which 4,017
207 remained significant after multiple testing correction (FDR correction, $q<0.1$). Using
208 greedy modularity optimization, a total of 4 subcommunities were identified in the full
209 network (Fig. 3d). We then studied the associations between these subcommunity modules
210 and NAFLD and identified one module that consists of 2 fungal (*Candida* CTG-clade and
211 *Saccharomyces*) and 9 bacterial genera (including *Ruminococcus*, *Dialister*, and
212 *Parasutterella* amongst others) that were significantly associated with NAFLD-related
213 parameters (fibroscan, AST, ALT, and GGT) (Fisher's Exact test, $P=0.049$, odds
214 ratio=3.580), suggesting the interplay of the two microbial kingdoms and NAFLD.

215

216 **High levels of the *Candida* CTG-clade in advanced fibrosis patients**

217 In order to investigate whether changes in the mycobiome composition may be associated
218 with liver fibrosis progression in more advanced stages of the disease, we classified the
219 subjects into early- or advanced- fibrosis groups using a cutoff fibroscan value of 9.7kPa³³.
220 We performed diversity analyses and found no significant differences (Wilcoxon rank-sum
221 test, $P>0.05$) in alpha diversity (Shannon and Simpson index) at the genus level. Beta
222 diversity analysis using Aitchison distance showed that the mycobiome composition at the
223 genus level between early and advanced fibrosis groups was significantly different
224 (PERMANOVA adjusted for age, gender, and obesity-related parameters, $P=0.007$, Fig.
225 4a). We explored further the mycobiome composition profiles (Fig. 4b) and discovered that
226 the *Candida* CTG-clade was significantly increased in the advanced compared to the early
227 fibrosis group even when accounting for age, gender, and obesity-related parameters
228 ($P_{wilcoxon}=0.0009$, Wilcoxon rank-sum test; $P_{glm}=0.002$, GLM adjusted, Fig. 4c). The trend
229 of increasing *Candida* CTG-clade abundance was also visible grouped by fibrosis stage as
230 obtained by histology (Extended Data Fig. 5). However, for fibrosis stage F3 and F4 the

231 sample size was relatively small for biopsied patients and thus this trend was not significant
232 (Kruskal-Wallis, $P=0.07$ for the antibiotic-free sample set and $P=0.086$ for the full cohort).

233 We calculated the beta diversity (Aitchison distance) of early and advanced fibrosis
234 groups using all subjects and not only the antibiotic-free subjects, and significant
235 differences were again identified (PERMANOVA adjusted, $P=0.007$, Extended Data Fig.
236 4b). A significant increase in *Candida* CTG-clade abundance was also found in advanced-
237 compared to early fibrosis (Wilcoxon rank-sum test, $P_{\text{wilcoxon}}=0.0007$; GLM adjusted,
238 $P_{\text{glm}}=0.002$) when analyzing the full cohort (Extended Data Fig. 4c). Our findings suggest
239 that in both, antibiotic-free and total study cohorts, *Candida* CTG-clade abundance is
240 significantly higher in the advanced fibrosis group, suggesting that this clade may
241 contribute to the progression of the disease.

242 We further explored the *Candida* CTG-clade imbalance in an advanced fibrosis
243 stage in the antibiotic-free set of samples and found an association between the
244 presence/absence of the *Candida* CTG-clade and the fibrosis stage (Fisher's Exact test,
245 $P=0.006$, odds ratio=3.097). We then performed regression analysis between the fibroscan
246 stiffness values and *Candida* CTG-clade abundance and found a significant association
247 (GLM adjusted for age, gender, and obesity-related parameters, $P=0.001$, estimate=0.22).
248 Correlation analysis also showed a positive significant correlation between fibroscan values
249 and *Candida* CTG-clade abundances (Spearman's correlation adjusted, $P=0.026$, $\rho=0.23$).
250 We then evaluated this association for the complete cohort of samples and the same results
251 were obtained (presence/absence of *Candida* CTG-clade associated with the fibrosis stage,
252 $P=0.002$, odds ratio=2.73, Fisher's Exact test; *Candida* CTG-clade abundances and
253 fibroscan, significant positive correlation, Spearman's correlation adjusted, $P=0.01$, $\rho=0.20$
254 and GLM adjusted, $P=0.002$, estimate=0.23, accounting for age, gender, obesity-related
255 parameters and antibiotic use).

256

257 **The IL-17A rs2275913 SNP influences IL-17 production in response to CTG-*Candida***

258 To determine whether the *IL-17A* rs2275913 SNP has functional relevance in responses to
259 the highly abundant *Candida* CTG-clade representatives and may be involved in NAFLD
260 pathogenesis, we stimulated freshly isolated T cells from rs2275913-genotyped healthy
261 donors with fungal lysates and measured the resulting IL-17A secretion. To ensure that
262 differences in T cell proportions among PBMCs of individual donors did not influence IL-
263 17A levels, we first isolated T cells and then used equal numbers of T cells in the stimulation
264 assays. An age-dependent influence on CD4⁺ T cell frequency was excluded due to similar
265 mean age of donors in genotype groups. T cells were stimulated with fungal lysates of
266 pathogenic (*C. albicans*) and non-pathogenic (*D. hansenii*) representatives of the *Candida*
267 CTG-clade^{34,35} as well as with PepTivator® *C. albicans*, a peptide pool of the major T cell
268 antigen MP65 of *C. albicans* (Extended Data Fig. 6b). IL-17A secretion was measured by
269 ELISA and calculated with a 4parameter standard fit curve (Extended Data Fig. 7). Both
270 fungal lysates induced IL-17A production, with T cells from individuals with the rs2275913
271 A/A genotype having significantly increased IL-17A levels in comparison to those with the
272 rs2275913 G/G and heterozygous genotypes (*C. albicans*: $P_{\text{Kruskal-Wallis}}=0.022$, $P_{\text{glm}}=0.088$;
273 *D. hansenii*: $P_{\text{Kruskal-Wallis}}=0.025$; $P_{\text{glm}}=0.040$, Fig. 5a-b). Thus, the IL-17A rs2275913
274 genotype modifies the amount of IL-17A produced in response to the *Candida* CTG-clade
275 species. Together with the elevated *Candida* CTG-clade abundance in NAFLD patients,
276 this suggests a combinatory effect of dysregulated antifungal immunity and imbalance in
277 *Candida* CTG-clade species on fibrosis development in patients with NASH.

278

279 **DISCUSSION**

280 In this study we investigated genetic variation in IL-17A and its interaction with the
281 intestinal mycobiome as a potential risk factor in NAFLD. Previous data from our group
282 indicate that the NAFL to NASH progression is marked by an increased frequency of IL-
283 17 producing cells among intrahepatic CD4⁺ T cells and higher Th17/resting regulatory T
284 cells (rTreg) ratio in peripheral blood⁷. Genotyping of our NAFLD cohort revealed a
285 significant association between the *IL-17A* rs2275913 variant and fibrosis severity. IL-17
286 is known as a profibrotic cytokine especially for liver fibrosis³⁶, and our data clearly suggest
287 that this may play a role in the pathogenesis of NASH. These data provide additional insight
288 into genetic risk factors that promote inflammation and fibrosis in NAFLD.

289 *C. albicans* is a potent trigger of Th17 responses. Increased intestinal *C. albicans*
290 abundance was positively correlated to systemic levels of fungal-specific Th17
291 inflammation measured by IL-17 producing CD4⁺ T cells. In this context, *C. albicans*
292 commensal gut colonization triggers a host defense that is cross-reactive against other
293 pathogens³⁷. Our results suggest that in combination with the *IL-17A* risk genotype,
294 increased *C. albicans* abundance could contribute to inflammation-driven liver fibrosis.

295 Intestinal mycobiome analysis additionally identified other *Candida* CTG-clade
296 species to be highly abundant in advanced fibrosis with similarly decreased *Saccharomyces*
297 abundance in these NAFLD patients. Importantly, a genus base taxon analysis should not
298 be used for polyphyletic genera such as *Candida*³⁸. Our results confirm recent mycobiome
299 analysis data generated by ITS2 sequencing but extend these with the taxonomically
300 relevant *Candida* CTG-clade grouping²³. Primer bias does not seem to have influenced
301 overall highly abundant fungal species but in our case ITS1 sequencing might have led to
302 missing e.g., *Malassezia* species detection³⁹. In the context of the overall intestinal
303 microbiome, microbial communities rather than single species can contribute to NAFLD
304 development as shown by our interaction analysis where we identified a subcommunity
305 module that includes *Candida* CTG-clade together with one more fungal genus and nine
306 bacterial genera that are jointly associated with NAFLD progression. In addition to
307 mycobiome dysbiosis in NASH patients, the composition of intestinal bacteria is altered in
308 NAFLD, suggesting the interaction of multiple components of the intestinal microbiome.
309 Future work should focus on characterization of possible interaction mechanisms to further
310 elucidate the role of intestinal fungi in NAFLD pathogenesis in relation to the multifactorial
311 nature of this disease. However due to the high intestinal mycobiome variability,
312 longitudinal and well-monitored studies are essential to exclude possible diet, antibiotic or
313 environmental-mediated effects and identify only causal intestinal mycobiome changes
314 associated with NAFLD pathogenesis.

315 Gastrointestinal or liver disease-associated mycobiome studies commonly involve
316 members of the *Candida* CTG-clade. Studies investigating alcohol-associated liver disease
317 (ALD) identified elevated abundance of *C. albicans* and *Debaryomyces* sp. in alcohol use
318 disorder patients in comparison to healthy controls. Interestingly, this fecal mycobiome
319 dysbiosis was improved by two weeks of abstinence⁴⁰. The *C. albicans*-derived exotoxin
320 candidalysin has been associated with the severity of liver disease in ALD patients²⁴, and a
321 recent study revealed that *C. albicans* strain diversity regulates the immune response in
322 inflammatory bowel disease⁴¹ indicating a crucial role for highly-abundant *C. albicans* in
323 other liver and gastrointestinal diseases. In mouse models of disease associated with
324 mycobiome dysbiosis, amphotericin B was identified as a promising treatment as it
325 counteracted mycobiome dysbiosis involving elevated abundance of *C. albicans* and *D.*
326 *hansenii*. In fecalmicrobiome humanized gnotobiotic mice, amphotericin treatment led to
327 decreased intestinal *C. albicans* abundance and improved diet-induced liver fibrosis and
328 steatohepatitis²³. In mice with Crohn's disease, *D. hansenii* was isolated in high abundance
329 directly from mucosal wound tissue and amphotericin B treatment not only reduced *D.*
330 *hansenii* abundance but also reversed the impaired crypt regeneration after injury⁴².

331 Mycobiome dysbiosis involving increased intestinal abundance of *D. hansenii* is of
332 particular interest, as the food-borne *D. hansenii* is often found on cheese as well as
333 processed meat in Western-style diet and is therefore often seen as a transient mycobiome
334 component. Although the possible probiotic properties of *D. hansenii* have been studied
335 intensively⁴³, its functional role in the context of human disease is still unknown and needs
336 to be characterized. However, it seems to possess Th17-stimulating potential, as our *ex vivo*
337 T cell stimulation assay demonstrated elevated IL-17A levels in response to *D. hansenii* in
338 rs2275913 minor allele variant carriers, similar to the increased IL-17A levels after *C.*
339 *albicans* stimulation. Therefore, our results suggest a combinatory effect of risk variant-
340 driven increased antifungal IL-17A response and elevated intestinal *Candida* CTG-clade
341 species abundance that may promote fibrosis in NASH patients and thereby further
342 elucidate the role of intestinal fungi in inflammatory-driven liver disease.

343 344 **METHODS**

345 **Patients (NAFLD cohort)**

346 In this prospective study, 451 NAFLD patients were enrolled between 2016-2019 in the
347 division of hepatology of the department of Medicine II, University Hospital Würzburg,
348 Germany. All study participants were >18 years old and diagnosed with NAFLD either by
349 histology (n=230) or clinically by transient elastography (TE; fibroscan & controlled
350 attenuation parameter (CAP) (n= 350). We included all clinically characterized NAFLD
351 subjects in our cohort irrespective of histological characterization to investigate
352 associations between genetic variations in antifungal immunity and gut mycobiome
353 imbalance with the largest possible sample size. Although liver histology is considered the
354 gold standard of NAFLD diagnosis, the more easily accessible TE is a widely used and
355 validated technique that has shown a high performance for the diagnosis and exclusion of
356 advanced fibrosis when compared to liver biopsy⁴⁴. Additionally, it reduces the imminent
357 risk of sampling error due to heterogeneous distribution of fibrosis when assessing liver
358 biopsy specimens⁴⁵.

359 Clinical and anthropometric characteristics of the study cohort are shown in Table
360 1. A cutoff for daily alcohol consumption was set (<20g/d for female and <30g/d for male
361 subjects) and further underlying liver disease (e.g. autoimmune liver disease or chronic viral
362 hepatitis) was excluded. Information on patients' last antibiotic treatment was documented.
363 Fecal, serum and whole blood samples were immediately snap-frozen and stored in the local
364 biobank.

365 366 **Ethics approval & consent to participate**

367 This study, involving the NAFLD patient cohort (University of Würzburg: EK 96/12,
368 05.09.2012; EK 188/17, 13.01.2020) and healthy volunteers (University of Würzburg: EK
369 191/21, 16.08.2021) was approved by the local ethics committee and conforms to the ethical
370 guidelines of the 1975 Declaration of Helsinki. We obtained written informed consent from
371 all patients and healthy volunteers included in this study.

372 373 **DNA extraction from blood and PBMCs and TaqMan SNP Genotyping**

374 DNA was extracted from frozen blood or PBMC samples using the Roche High Pure PCR
375 Template Preparation Kit (Sigma Aldrich, #11796828001) according to the manufacturer's
376 instructions. Isolated DNA was then used in TaqMan SNP Genotyping Assays
377 (ThermoFisher, CN #4351376; CARD9 (ID: C_25956930_20), CLEC7A (ID:
378 C_33748481_10), IL-17A rs2275913 (ID: C_15879983_10) according to
379 manufacturer's instructions. Assays were conducted with the qTower³ (Analytik Jena) and
380 analyzed with the qPCRsoft 3.4 software (Analytik Jena). The functionality of TaqMan

381 SNP Genotyping was confirmed by additional sequencing of 5% samples and validating
382 the obtained genotypes. For sequencing, a 414 bp part of interest in the IL-17A gene
383 was amplified (5': ATATGATGGGAAGTCTGAGTAGTTTCCG, 3':
384 CTCCTTCTGTGGTCACTTACGTGG) with 2x Q5 polymerase master mix according to
385 the manufacturer's instructions (NEB, #M0492L). PCR samples were purified with the
386 PCR & Gel Clean-Up Kit (Macherey-Nagel, #740609.50) according to the manufacturer's
387 instructions and sent to LGC genomics for sequencing with the 5' primer. DNA sequences
388 were evaluated with ApE (v.3.0.8).

389

390 **PBMC and T cell isolation**

391 Freshly drawn blood from healthy volunteers was diluted 1:1 in PBS / 1 mM EDTA
392 (Invitrogen, ThermoFisher Scientific: #AM9260G) containing 1% inactivated human AB
393 serum (Sigma Aldrich, #H4522-100ML) and separated via Biocoll density gradient
394 medium (Bio&SELL, #BS.L 6115) in SepMate tubes (Stemcell Technologies, #85460)
395 according to the manufacturer's instructions. Afterwards, PBMCs were washed 3 times
396 with PBS-EDTA-human serum mix. As T cell proportions vary strongly between individual
397 PMBC donors, we additionally isolated T cells before stimulation and IL-17A secretion
398 measurement.

399 T cells were isolated from freshly isolated PBMCs by negative selection with the
400 human Pan T Cell Isolation Kit (Miltenyi, #130-096-535) according to manufacturer's
401 instructions and the purity of >90% was assessed by flow cytometry (Miltenyi MACSQuant
402 [®]).

403 PBMC and T cell number and cell viability were measured directly after isolation
404 with the LUNA automated cell counter (Logos Biosystems) and the viability was in each
405 case >99%.

406

407 **Preparation of fungal lysates**

408 50ml inoculated YPD medium (20g/L glucose, 20g/L peptone, 10g/L yeast extract) was
409 cultured overnight at 25°C (*D. hansenii* CBS767) and 37°C (*C. albicans* SC5314). The
410 overnight culture was diluted 1:50 in 50ml YPD medium and thereafter cultured for 5h.
411 Cells were harvested by centrifugation at 4.000g for 10min and the cell pellet was
412 resuspended in lysis buffer (50mM Tris-HCl, 150mM NaCl, 0.1% Triton X-100, 1mM
413 DTT, 10% glycerol) with freshly adjusted proteinase inhibitor (Sigma, #S8820-20TAB).
414 For lysis, 500µl glass beads were added per tube and five 1min vortexing steps were
415 followed by five 1min cooling steps on ice. After centrifugation at 20000g for 5min the
416 supernatant was transferred to a fresh reaction tube and stored in aliquots at -80°C. The
417 protein concentration was measured with the Qubit protein assay kit (Invitrogen,
418 ThermoFisher Scientific: #Q33211).

419

420 **T cell stimulation and measurement of IL-17A**

421 Freshly isolated T cells were plated at 2×10^6 cells/well in 48-well plates and stimulated with
422 40µg/ml *C. albicans* SC5314 lysate, 40µg/ml *D. hansenii* CBS767 lysate, 1µg/ml
423 PepTivator[®] *C. albicans* mp65 peptide pool mix (Miltenyi, #130-096-776), or medium as
424 a negative control, in a final volume of 500µl. For the positive control, wells were precoated
425 with 1µg/ml antihuman CD3 antibody (Miltenyi, #130-093-387) at 37°C for 2h. All wells
426 were supplemented with 1µg/ml anti-human CD28 antibody (Miltenyi, #130-093-375). The
427 plates were incubated for 48h at 37°C with 5% CO₂. All samples were prepared in
428 duplicates. After incubation, supernatants were frozen at -80°C until IL-17A measurement.
429 Antigen-specific IL-17A levels were measured in thawed supernatants in duplicate using
430 the IL-17A ELISA kit (Invitrogen, ThermoFisher Scientific: #BMS2017) according to the

431 manufacturer's instructions. The standard curve was calculated from blank-curated mean
432 standard values with a 4-parameter curve fit (R package *dr4pl*, v2.0.0). All sample values
433 were blank-curated before concentration calculation via the standard curve formula.

434

435 **Fecal DNA extraction, internal transcribed spacer 1 and 16S rRNA sequencing**

436 Microbial DNA was extracted from stool samples using the DNeasy PowerSoil Kit
437 (Qiagen, #12888-100) according to the manufacturer's instructions. We divided the sample
438 into 4 subsamples to increase efficiency of the beat-beating step.

439 The Illumina platform Miseq V3 with paired-end reads of 300 bp was used for all
440 samples. For the ITS sequencing samples were processed by LGC Genomics GmbH. The
441 ITS1 region was amplified using ITS1F/ITS2R primers. The total read count was on
442 average 54,000 reads/sample. From the 246 total 16S rRNA sequencing samples, 149 16S
443 rRNA sequencing samples that had not been previously analyzed were processed by LGC
444 Genomics GmbH using sequencing primers 341F-785R, targeting the V3-V4 region. The
445 total read count was on average 56,000 reads/sample. 97 16S rRNA sequencing samples
446 from a previous study were processed as described in Rau et al¹⁵.

447

448 **Taxonomic profiling**

449 Taxonomic annotation of fungal Internal Transcribed Spacer (ITS) was performed using
450 the PIPITS pipeline⁴⁶ version 2.4, with default parameters including quality filtering, read-
451 pair merging, ITS1 extraction and chimera removal. Remaining reads were binned based
452 on 97% similarity as operational taxonomic units (OTUs) and aligned with QIIME⁴⁷ to the
453 UNITE fungi database⁴⁸ using *mothur* classifier. Samples were then normalized by
454 cumulative sum scaling using the R package *metagenomeSeq*. Due to the complex fungal
455 taxonomy, we grouped fungi according to genus but used the CTG-clade to characterize the
456 *Candida* genus.

457 For the 16S rRNA sequencing data, quality control to remove low-quality reads and
458 taxonomic annotation was performed using QIIME⁴⁷. Raw reads were joined and trimmed
459 with *cutadapt* to remove the primer sequences. *Deblur* workflow was used for filtering and
460 denoising the joined reads. Assigning taxonomic information to each amplicon sequence
461 variant (ASV) was performed using a Naive Bayes classifier with 99% similarity in QIIME.
462 The classifier was fitted to the appropriate rRNA gene region (V3-V4) with the SILVA 132
463 database⁴⁹.

464

465 **Diversity analysis**

466 Alpha diversity indices detailing mycobiome community composition within samples were
467 calculated using the R package *vegan*. Testing for significant differences in alpha diversity
468 was performed using Wilcoxon rank-sum test. For estimating beta diversity reflecting
469 community dissimilarities, *cmultRepl* function from R package *zCompositions* was first
470 used to perform Bayesian-Multiplicative replacement of count zeros to the raw OTU table.
471 Aitchison distances were calculated using *aDist* function from the R package
472 *robCompositions*. We performed Partial Least Squares Discriminant Analysis (PLS-DA)
473 using the mycobiome Aitchison distance matrix with the R package *mixOmics*. To test for
474 significant differences in the mycobiome composition, permutational multivariate analysis
475 of variance (PERMANOVA) as implemented in the function *adonis* from R package *vegan*
476 adjusting for age, gender, obesityrelated parameters (age, gender, BMI, DM, aHT and
477 hyperlipidemia) was used. Mycobiome community and clinical data (age, gender, height,
478 weight, BMI, AST and ALT) were fit onto the ordination using the function *envfit* from
479 *vegan* R package.

480

481 **Statistics**

482 Associations between the SNP genotypes and fibroscan values or grouped fibrosis (cutoff
483 9,7kPa) were investigated with generalized linear models adjusting for age, BMI, gender
484 and PNPLA3 rs738409 with the *glm* function of the R package stats. Due to its potential as
485 a genetic risk factor for NAFLD²⁷, we additionally adjusted for the PNPLA3 rs738409
486 genotype in all SNP-based generalized linear model (*glm*) calculations. The PNPLA3
487 rs738409 genotyping data was available for samples of our NAFLD patient cohort data but
488 were generated in a previous study²⁸. Statistical analysis of this data with the *glm* function
489 confirmed primary findings from this study (Fig. 2c).

490 Correlations between mycobiome and clinical data were assessed by Spearman's
491 correlation adjusting for age, gender, and obesity-related parameters (age, sex, BMI, DM,
492 aHT and hyperlipidemia) using the function *pcor.test* from R package ppcor. Differentially
493 abundant genera were identified by the Wilcoxon rank-sum test using R package stats, and
494 by a generalized linear model adjusting for previously mentioned parameters (genus ~
495 fibroscan.group + age + gender + BMI + DM + aHT + hyperlipidemia), with *glm* function
496 from R package stats. Association between the presence or absence of *Candida* CTG-clade
497 and the fibrosis state was calculated by the Fisher test, using the *fisher.test* function from R
498 package stats. A generalized linear model adjusting for previously mentioned parameters
499 was used to study the association between *Candida* CTG-clade and fibroscan value (genus
500 ~ fibroscan + age + gender + BMI + DM + aHT + hyperlipidemia), with *glm* function from
501 R package stats. When exploring all data, the antibiotic intake was included for adjustment
502 when appropriate.

503

504 **Microbiome community network analysis**

505 In order to explore the associations between microbial genera and NAFLD progression, we
506 built a correlation network using mycobiome and bacteriome data. To build the correlation
507 network, the *correlate_fastspar* function from R was used. The SparCC method was used
508 to calculate the interactions between pairs of co-abundant taxa. The significance threshold
509 for correlations was set to 0.05. Clustering of the network taxa was performed using
510 *cluster_fast_greedy* function from igraph R package. Correlations between taxa and clinical
511 variables (fibroscan, weight, AST, ALT and GGT) were calculated using *pcor.test* adjusting
512 for age, gender and obesity-related parameters. To explore the association between clusters
513 and NAFLD, the *fisher.test* function from R package stats was used. A fungal/bacterial
514 genus was considered to be correlated with NAFLD progression if there was at least one
515 significant correlation with fibroscan, AST, ALT or GGT.

516

517 **Data visualization**

518 Figures were generated by R software 3.6.3, using ggplot2 package.

519

520 **DATA AVAILABILITY**

521 Raw sequences from ITS1 gene sequencing were registered at NCBI under BioProject
522 PRJNA834619.

523

524 **ACKNOWLEDGMENTS**

525 This project was funded by the IZKF Würzburg (project A-401), the Marie Skłodowska-
526 Curie Actions (MSCA), and Innovative Training Networks, H2020-MSCA-ITN-2018,
527 813781 "BestTreat". GP would like to thank the Deutsche Forschungsgemeinschaft (DFG,
528 German Research Foundation) under Germany's Excellence Strategy for intellectual input.
529 We want to thank Carolin Spielau-Romer and Lea Strobel for their contribution to this
530 project.

531

532 **AUTHOR CONTRIBUTIONS**

533 O.K., A.G., and T.D. conceived and designed the study. A.G., H.H., and M.R. recruited the
534 participants and were responsible for clinical data collection. M.R. and H.H. collected fecal
535 samples and extracted DNA from feces together with N.T.. A.M.A., and M.H. collected
536 blood samples for the T cell stimulation assay, J.L. provided additional samples for this
537 assay. H.H. and N.T. extracted DNA from blood and PBMC samples. R.M. and N.E.N.
538 were involved in planning of experimental analyses. N.T. performed and analyzed the
539 experimental analyses. S.L.S. and M.M. performed the metagenomics analyses. O.K., G.P.,
540 and A.G. led and supervised the research work. N.T. and S.L.S. wrote the manuscript. G.P.,
541 O.K., A.G., and M.R. edited the manuscript. All authors reviewed and made substantial
542 contributions and approved the final version of the manuscript.

543

544 **COMPETING INTERESTS**

545 The authors declared no conflict of interest.

546

547 **ABBREVIATIONS**

548 aHT: arterial hypertension, ALD: alcohol-associated liver disease, ALT: alanine
549 aminotransferase, AST: aspartate aminotransferase, BCAA: branched-chain amino acid, *C.*
550 *albicans*: *Candida albicans*, *D. hansenii*: *Debaryomyces hansenii*, GLM: generalized linear
551 model, HC: healthy control, MAF: minor allele frequency, NAFL: non-alcoholic fatty liver,
552 NAFLD: non-alcoholic fatty liver disease, NASH: non-alcoholic steatohepatitis, OTU:
553 operational taxonomic unit, TE; transient elastography, rTreg: resting regulatory T cells,
554 *S.cerevisiae*: *Saccharomyces cerevisiae*, SCFA: short-chain fatty acid

Overview

In manuscript IV, we aimed to explore the potential value of the gut microbiome in the development of NAFLD and to build a machine learning model able to predict individuals at risk to develop NAFLD four years later. We demonstrated differences in the microbiome signature and metabolic shifts in subjects that will develop NAFLD compared to controls. In addition, we presented a machine learning model able to predict the progression to NAFLD with an auROC of 0.80. These results showed the biological relevance of the gut microbiome and potential microbial markers for early NAFLD diagnosis.

A growing body of evidence suggests interplay between the gut microbiota and the pathogenesis of nonalcoholic fatty liver disease (NAFLD). However, the role of the gut microbiome in early detection of NAFLD is unclear. Prospective studies are necessary for identifying reliable, microbiome markers for early NAFLD. We evaluated 2487 individuals in a community-based cohort who were followed up 4.6 years after initial clinical examination and biospecimen sampling. Metagenomic and metabolomic characterizations using stool and serum samples taken at baseline were performed for 90 participants who progressed to NAFLD and 90 controls who remained NAFLD free at the follow-up visit. Cases and controls were matched for gender, age, body mass index (BMI) at baseline and follow-up, and 4-year BMI change. Machine learning models integrating baseline microbial signatures (14 features) correctly classified participants (auROCs of 0.72 to 0.80) based on their NAFLD status and liver fat accumulation at the 4-year follow up, outperforming other prognostic clinical models (auROCs of 0.58 to 0.60). We confirmed the biological relevance of the microbiome features by testing their diagnostic ability in four external NAFLD case-control cohorts examined by biopsy or magnetic resonance spectroscopy, from Asia, Europe, and the United States. Our findings raise the possibility of using gut microbiota for early clinical warning of NAFLD development.

INTRODUCTION

Since the 1980s, the prevalence of obesity, insulin resistance, type 2 diabetes mellitus, and obesity-associated nonalcoholic fatty liver disease (NAFLD) has grown worldwide (1–3). The occurrence of these interconnected diseases is partly driven by consumption of high-energy food and a sedentary lifestyle, and these diseases are considered critical global health and socioeconomic problems (4). Apart from associations with liver-related diseases, epidemiological studies have associated NAFLD with increased risk of developing extrahepatic chronic diseases, such as type 2 diabetes, cardiovascular disease, and chronic kidney disease (5, 6). A recent cohort study showed that overall mortality risk increases progressively with worsening NAFLD histology, and even simple steatosis increases

mortality risk by 71% (7), thus simple steatosis can no longer be considered as benign as previously thought (8). Although NAFLD affects about 25% of the world's population (9) and has a high disease burden, awareness of NAFLD is low. In a cross-sectional analysis ($n = 2788$) in four U.S. cities, NAFLD prevalence was 23.9%, whereas awareness of NAFLD was 2.4% in study participants with computed tomography (CT)-defined NAFLD (10). One important reason for low awareness is that most patients with NAFLD are largely asymptomatic in the disease course, where disease is mainly detected through an incidental finding of fatty liver on ultrasound or an imaging modality or routine laboratory testing (11, 12). Diagnosis by liver biopsy or imaging is reliable but difficult for large-scale screening and monitoring. Thus, the need to identify individuals who are at high risk of developing NAFLD or are at an early stage of the disease is urgent, as lifestyle interventions can reverse the disease when it is in the first stages (13). According to one study (14), weight loss and healthy diet might be sufficient to reverse simple steatosis, whereas intensified lifestyle intervention coupled with pharmacological treatment might be necessary for more advanced stages of liver diseases. Exercise programs (15), low-carbohydrate diet (16), and various types of gut microbiota-targeted treatments (17) have demonstrated their ability to prevent steatosis development and improve NAFLD outcomes in human or preclinical models. Early diagnosis and interventions to prevent NAFLD progression can also greatly reduce future health care cost, as most economic costs associated with NAFLD are incurred in advanced stages (18). Currently available methods (19–21) for early prediction of NAFLD are limited and use only a few clinical parameters or biomarkers that may not reflect the heterogeneity and complexity of NAFLD (22, 23). Thus, more convenient noninvasive alternatives are needed.

In the last 10 years, the gut microbiome has emerged as a major regulator of host energy homeostasis and substrate metabolism (24–26). The human gastrointestinal tract is colonized with 4644

bacterial species encoding 171 million genes (27). Therefore, it is not unexpected that abnormalities in gut microbiome structure and especially function might affect the brain, adipose tissue, muscle, and liver metabolism. Microbial components or metabolites such as lipopolysaccharides, secondary bile acids, dimethyl- and trimethyl-amines, and compounds derived from carbohydrate and protein fermentation appear to be strongly involved in the gut host-microbiome metabolic axis and the occurrence of metabolic diseases (28–31).

Human cross-sectional studies have delineated the role of gut bacteria in the development of NAFLD. An increased ratio of Bacteroidetes to Firmicutes phyla and a decrease in butyrate-producing *Ruminococcaceae* are suggested to be involved in NAFLD progression; however, the data are not always consistent (32–35). Furthermore, whether NAFLD causes taxonomic and functional changes in the microbiome or the observed dysbiosis in patients with NAFLD leads to progression of the disease is not clear. For a possible causal role in NAFLD development, gut microbiota alteration should take place long before disease is diagnosed, which would suggest prognostic value in evaluating the gut microbiome in individuals with a high risk of developing NAFLD. To assess this potential value, we conducted a 4-year prospective study in a community-based cohort of 2487 Chinese individuals. We profiled 180 matched case-control individuals who were NAFLD free at baseline using well-documented clinical information and comprehensive metagenomic and metabolomic analysis. We developed machine learning models integrating baseline microbial signatures to classify individuals based on their NAFLD status 4 years after baseline (either remaining disease free or diagnosed with the disease). We also examined whether the selected features in the model were biologically relevant to NAFLD development by exploring the diagnostic power of the model in several case-control cohorts from Asia, the United States, and Europe.

RESULTS

Characterization of the study cohort

To develop a microbiome-based prognostic model for long-term development of NAFLD, we designed a nested case-control study within a community-based prospective cohort study of Chinese adults. About 2500 participants were screened in 2014 with ultrasonography, which is recommended as the first-line diagnostic test for NAFLD (36); 1216 participants were determined as NAFLD free using criteria proposed by the Asian Pacific Association for the Study of the Liver (37). Participant enrolment is outlined in fig. S1. Stool and serum samples were obtained from participants at baseline. At the follow-up visit in 2018, after a strict exclusion process, 90 participants (38 males and 52 females) were identified as having NAFLD (NAFLD^{+/+}) (Fig. 1). The participants in the NAFLD^{+/+} group were matched with 90 controls who did not have NAFLD at baseline or at the follow-up visit (NAFLD^{-/-}). The two groups were matched in gender, age, and body mass index (BMI) at both the baseline and follow-up visits and 4-year change in BMI. There were no differences between the two groups in the prevalence of type 2 diabetes, hypertensive disease, metabolic syndrome, and medication usage at both baseline and follow-up in the cohort, apart from a significantly higher metabolic syndrome ratio in NAFLD^{+/+} at follow-up as expected (chi-square test, $P < 0.05$; table S1).

Detailed baseline anthropometric parameters, glucose homeostasis parameters, serum liver enzymes and renal function, lipid profiles, and cytokines are shown in Table 1. No significant differences (t test, $P > 0.05$) were seen for most clinical parameters between the NAFLD^{+/+} and NAFLD^{-/-} groups at baseline. Fasting insulin (FINS), homeostasis model assessment for insulin resistance (HOMA-IR), triglycerides (TGs), and high-sensitivity C-reactive protein (hs-CRP) in the NAFLD^{+/+} group were slightly higher than in the NAFLD^{-/-} group

Fig. 1. Overview of the prospective study design. A graphical representation summarizing the study design, data collection, and the methodologies of data generation and analysis. Further details of the study design can be found in fig. S1.

Table 1. Baseline characteristics of participants in NAFLD^{-/+} and NAFLD^{-/-} groups. Data are expressed as means ± SD or median (lower quartile and upper quartile) for continuous variables, and *n* represents percentage for categorical variables. *P value denotes differences between NAFLD^{-/+} and NAFLD^{-/-} analyzed by *t* test without adjustment. †P value denotes differences between NAFLD^{-/+} and NAFLD^{-/-} analyzed by analysis of covariance with HOMA-IR adjusted. ‡Log-transformed before analysis.

(t test, $P < 0.05$); however, their mean or median values were within reference ranges in both groups (FINS: 5.1 to 11.2 uU/ml, HOMA-IR < 2.5 , TG < 1.70 mM, and hs-CRP < 1 μ g/ml) (38–41). Only TGs remained significantly different after adjusting for HOMA-IR (1.55 ± 0.90 mM versus 1.23 ± 0.61 mM; Table 1).

Modest but distinguishable differences in baseline gut microbiome between NAFLD^{+/-} and NAFLD^{-/-} individuals

We assessed the gut microbiome structure of the NAFLD^{+/-} and NAFLD^{-/-} groups at baseline via shotgun metagenomic sequencing, generating 1128 gigabase pairs of high-quality reads with an average of 41,786,187 reads per sample (Fig. 1). Taxonomic profiling with MetaPhlan2 (42) led to the identification of 405 species. Community alpha diversity measured as richness, and Shannon and Simpson indexes showed no significant differences (Wilcoxon rank-sum test, $P > 0.05$) at the species, genus, or family levels between the two groups (fig. S2A). Bray-Curtis, unweighted UniFrac, and weighted UniFrac distance comparisons indicated that the NAFLD^{+/-} and NAFLD^{-/-} groups did not have significant community dissimilarities [permutational multivariate analysis of variance (PERMANOVA), $P > 0.05$; fig. S2, B and C]. The same patterns were observed when using a metagenomic species approach (43) for the taxonomic annotation (table S2).

In addition, we sequenced the baseline gut microbiota from 66 participants who were diagnosed as NAFLD in both 2014 and 2018 (NAFLD^{+/+}) and 34 participants who were diagnosed as NAFLD in 2014 but not in 2018 (NAFLD^{+/-}). These two groups were also matched with the other two groups described above by age, gender, BMI, and 4-year change in BMI. A thorough comparison of microbiota alpha and beta diversity among the four groups at baseline indicated that the two non-NAFLD groups were distinguishable from the two NAFLD groups ($P < 0.05$, Wilcoxon rank-sum test for alpha diversity comparisons and PERMANOVA for beta diversity comparisons using Bray-Curtis distances) (fig. S3). Moreover, the gut microbiota of NAFLD^{+/+} subjects was different from that of NAFLD^{+/-} and NAFLD^{-/-} individuals. This argues that the NAFLD^{+/-} group was not already diseased at the baseline because they clustered with NAFLD^{-/-} subjects at baseline. Because our focus was to identify gut microbiota signatures in disease-free individuals suggestive of NAFLD predisposition, only the NAFLD^{-/-} and NAFLD^{+/-} groups were further analyzed.

A compositional analysis found that several of the 10 most abundant genera and species (Fig. 2A) were significantly associated (envfit from R package vegan, $P < 0.05$) with observed variation in the taxonomic profile of the study participants (fig. S2, B and C). However, their relative abundances were not significantly different (zero-inflated Gaussian mixture model, $P > 0.05$) between NAFLD^{+/-} and NAFLD^{-/-} groups. Nevertheless, the relative abundances of 8 and 21 less-abundant genera and species, respectively, were significantly different (zero-inflated Gaussian mixture model, $P < 0.05$) between the two groups (fig. S2D). *Methanobrevibacter* [false discovery rate (FDR) = 0.01] was decreased in NAFLD^{+/-} compared to NAFLD^{-/-} (a reduction in *Phascolarctobacterium* was insignificant at FDR = 0.2). Lower abundances of these two genera have been observed in cohort studies in obese individuals compared to lean individuals (44, 45). *Slackia* has been reported to be more abundant in individuals with moderate-to-severe fibrosis than in individuals with absent-to-mild fibrosis (46), and this genus was increased in the NAFLD^{+/-} compared to the NAFLD^{-/-} group (FDR = 0.06). The relative abundance of *Dorea formicigenerans*, a species that is highly abundant in people with obesity

(47), was higher in the NAFLD^{+/-} than the NAFLD^{-/-} group (FDR = 0.17). Differences in the relative abundances of *Methanobrevibacter*, *Phascolarctobacterium*, *Slackia*, and *D. formicigenerans* between the two study groups remained significant even after adjusting for age, gender, BMI, and HOMA-IR (zero-inflated Gaussian mixture model, $P < 0.05$). Because the NAFLD^{+/-} and NAFLD^{-/-} groups had no difference in BMI and in the aforementioned cohort studies, the liver status of the obese individuals was not evaluated, and our prospective design suggested that *Methanobrevibacter*, *Phascolarctobacterium*, *Slackia*, and *D. formicigenerans* could be signatures of NAFLD risk in addition to being obesity-related signatures.

We used HUMAnN2 (48) for functional profiling of the microbial communities and identified 458 pathways. Likewise, the taxonomic profile and the microbiota functional potential could not differentiate between NAFLD^{+/-} and NAFLD^{-/-} groups by alpha and beta diversity (fig. S4, A and B). Four of the most abundant pathways detected, uridine monophosphate biosynthesis I, uridine diphosphate-N-acetylmuramoyl-pentapeptide biosynthesis I and II, and peptidoglycan biosynthesis I (Fig. 2A), were significantly associated with observed variation in the functional profiles of study participants (envfit from R package vegan, $P < 0.05$; fig. S4B). These pathways were proposed to be discriminatory for NAFLD cirrhosis against control groups in a recent U.S. cohort study (49); however, their relative abundances were not significantly different (zero-inflated Gaussian mixture model, $P > 0.05$) between the NAFLD^{+/-} and NAFLD^{-/-} groups in our prospective study. Nevertheless, we found 19 biosynthetic pathways significantly different in relative abundance between the two groups (zero-inflated Gaussian mixture model, $P < 0.05$) (fig. S4C). We observed a significantly higher relative abundance of geranylgeranyl diphosphate biosynthesis and the mevalonate pathway in the NAFLD^{-/-} group. These pathways are dysregulated in mice and humans with nonalcoholic steatohepatitis (NASH) (50). Two genes encoding enzymes involved in these pathways, hydroxymethylglutaryl-coenzyme A (CoA) reductase (EC 1.1.1.34) and mevalonate kinase (EC 2.7.1.36), were significantly enriched in the NAFLD^{-/-} group (zero-inflated Gaussian mixture model, $P < 0.05$; table S3). *Methanobrevibacter smithii* was the major contributor of gene expression abundance of hydroxymethylglutaryl-CoA reductase (95%) and mevalonate kinase (40%). In contrast, the NAFLD^{+/-} group had a higher relative abundance of phosphatidate metabolism and cholic acid degradation. Cholic acid is a primary bile acid that decreases substantially in rats on a Western diet and is proposed as an early marker of NAFLD development (51). Genes encoding phospholipase D (EC 3.1.4.4) and bile-acid-7- α -dehydratase (EC 4.2.1.106) were also significantly enriched in the NAFLD^{+/-} group (zero-inflated Gaussian mixture model, $P < 0.05$, table S3). The four significant pathways above (geranylgeranyl diphosphate biosynthesis, mevalonate pathway, phosphatidate metabolism, and cholic acid degradation) remained significantly different (zero-inflated Gaussian mixture model, $P < 0.05$) between the two groups after adjusting for age, gender, BMI, and HOMA-IR, except for cholic acid degradation that was marginally significant ($P = 0.050$).

Metabolite enrichment and metabolic shifts in NAFLD^{+/-} versus NAFLD^{-/-} groups

We next performed targeted metabolomic analysis of serum samples collected at baseline to interrogate whether differences in species and pathway abundance of gut microbiota led to distinct profiles of microbial metabolites in the NAFLD^{+/-} and NAFLD^{-/-} groups. We

Fig. 2. Global characteristics of gut microbiome and serum metabolome. (A) Relative abundance of the 10 most abundant genera, species, and pathways for the 180 participants at baseline, grouped by NAFLD status at the follow-up visit. Anthropometric characteristics of the participants at baseline are also shown. Abundance values are normalized to the range of 0 and 1. (B) Changes of metabolites (μM) in metabolite classes containing at least 10 metabolites. Each point represents a metabolite and its z score from Wilcoxon rank-sum test comparing the two groups (negative indicates higher abundance in NAFLD^{-/-}; positive indicates higher abundance in NAFLD^{+/-}). Dotted lines at -1.96 and 1.96 denote the significance threshold. Colors indicate comparisons between z scores of metabolites in a metabolite class against the z scores of metabolites in all other classes. Box plots show median, lower/upper quartiles, and whiskers (the last data points 1.5 times interquartile range from the lower or upper quartiles). (C) Principal coordinates analysis for 180 participants based on Bray-Curtis distances using baseline serum concentrations of 123 metabolites. For each metabolite class, the top 3 (or fewer) metabolites that were significantly associated with the metabolome variation in the study cohort are shown. PC, principal coordinates.

detected 123 metabolites grouped into nine metabolite classes (Fig. 2B). We performed enrichment analysis to identify metabolite classes that were significantly overabundant or underabundant in the NAFLD^{-/-} or the NAFLD^{+/-} group, and found amino acids were significantly elevated in the NAFLD^{+/-} group (Wilcoxon rank-sum test, $P < 0.05$; table S4). We further analyzed the untargeted metabolomic data of

a European case-control cohort (MICROBARIA) involving 52 obese women including 26 with biopsy-confirmed NAFLD and 26 non-NAFLD (52). Two amino acids positively correlated with NAFLD-related liver enzymes, including the branched-chain amino acid valine with alanine transaminase (ALT) ($P < 0.05$, Spearman correlation) and the aromatic amino acid tyrosine with aspartate transaminase

(AST) ($P < 0.05$, Spearman correlation). Our findings in the Asian prospective and European cohort-based datasets are further supported by recent metabolomic-based studies, suggesting that perturbations in amino acid metabolism are involved in NAFLD and NASH pathogenesis (53–55).

Of the 15 significantly different metabolites between the NAFLD^{-/+} and NAFLD^{-/-} groups at baseline (generalized linear model, $P < 0.05$; fig. S5A) and the metabolites that were significantly associated with the observed metabolomic variation (envfit from R package vegan, $P < 0.05$; Fig. 2C), several are reported to be involved in NAFLD in case-control human or animal studies. For example, 3-chlorotyrosine, arachidonic acid, and oxoglutaric acid are markers, respectively, of liver damage and NAFLD development in mouse (56) and rat (57) models and a human NAFLD study (58). Tryptophan was also significantly associated with the metabolome variation (envfit from R package vegan, $P < 0.05$; Fig. 2C) in our cohort, and aromatic amino acids have been associated with NAFLD (54). These metabolites were higher in the NAFLD^{-/+} group than the NAFLD^{-/-} group. Concentration of a gut microbiota-regulated fatty acid, 8,11,14-eicosatrienoic acid, linked to obesity and insulin resistance (59, 60), was also significantly higher (generalized linear model, $P < 0.05$; fig. S5A) in the NAFLD^{-/+} group in our prospective study. Phenyllactic acid, produced by lactic acid bacteria and suggested to reduce reactive oxygen species production in rodents (61), was significantly higher in the NAFLD^{-/-} group (generalized linear model, $P < 0.05$; fig. S5A). On the contrary, the direction of concentration differences in the two study groups for isovaleric and docosahexaenoic acids (both higher in NAFLD^{-/+}) (generalized linear model, $P < 0.05$; fig. S5A) was inconsistent with proposals in the literature from case-control NAFLD studies about the possible roles of these compounds (62–64). These agreements and discrepancies in metabolite abundances in our prospective study with case-control cohort and mouse studies in the literature should help to narrow the metabolic marker possibilities for NAFLD progression. The concentrations of additional fatty acids were significantly different between the NAFLD^{-/+} and NAFLD^{-/-} groups (fig. S5A), but the functional significance of these metabolites in NAFLD is relatively unknown. Last, the concentrations of measured serum metabolites such as 3-chlorotyrosine and phenyllactic acid were significantly associated with gut microbiota species composition (Mantel test, $P < 0.05$; fig. S5B and table S5).

A machine learning prospective model to detect early signatures of NAFLD

We built a noninvasive risk assessment model (random forest algorithm) to classify healthy subjects based on their NAFLD status after 4.6 years, using a combination of baseline metagenomic and metabolomic features. A leave-one-out iterative approach was applied to build and evaluate our model due to the relatively small cohort size ($n = 180$). We built a prospective model using 14 taxonomic, functional, and metabolomic features of the study participants at baseline that enabled classification based on their NAFLD status 4.6 years later with an area under the receiver operating characteristic curve (auROC) of 0.72 (Fig. 3A). The performance of the model was significantly improved to an auROC of 0.79 (DeLong test, P value for difference < 0.05) with the addition of only two more noninvasive clinical features (Fig. 3B). We then slightly improved our model by also including the most accessible anthropometric parameters, BMI and age, to obtain our final model (auROC, 0.80; Fig. 3C and fig. S6).

We evaluated the biological relevance of the selected features by testing the diagnostic ability of components of our model to distinguish between healthy individuals and patients with NAFLD in two publicly available independent external Asian case-control cohorts; one cohort was diagnosed by biopsy and the other was diagnosed by magnetic resonance spectroscopy (MRS). This allowed us to further explore whether the patient diagnosis method had an impact on the model performance. We built a new prospective model using only nine features from the final model that were available in these external cohorts (fig. S6). The new model derived based on our study cohort discriminated healthy and NAFLD groups in the two external cohorts with auROCs of 0.78 and 0.72 (Fig. 3, D and E), showcasing that the features we identified were closely related to NAFLD development or pathophysiology. Besides the Asian cohorts, we further validated our prospective model in other case-control cohorts of different ethnicity. In the European cohort FLORINASH (54), the model (with the same nine features as in the Asian cohorts) reached an auROC of 0.76 (Fig. 3F), whereas in a U.S. cohort (49), the validation auROC (with seven available features) was 0.78 (Fig. 3G). Taking into consideration that only no more than half of features in our original prospective model were available in the external cohorts, we expect that the true accuracy may be higher.

Previous clinical prospective NAFLD studies demonstrated that fibroblast growth factor 21 and BMI (FGF21 + BMI), fatty liver index (FLI), and TG and glucose index (TyG) predict NAFLD development from 3 up to 9 years before diagnosis (auROCs of 0.71 to 0.82) (19–21). We compared the performance of our prospective model with FGF21 + BMI, FLI, and TyG to predict NAFLD occurrence in our cohort with matched baseline characteristics. The performance of our final model (auROC, 0.80) was significantly better than all three clinical models (auROCs of 0.58 to 0.60, P values for difference < 0.01 ; Fig. 3, H to J). To confirm the importance of metagenomic and metabolomic information in prospective NAFLD prediction, we added metagenomic and metabolomic features from our final prospective model to the clinical models (fig. S6) and observed significant improvements in all (auROCs of 0.73 to 0.75, P values for difference < 0.05 ; Fig. 3, H to J); however, none of the models reached the auROCs of our final model.

In total, 18 features were used in the final model: two genera, three pathways, nine metabolites, and four anthropometric and clinical parameters (Fig. 4, A and B). Our analysis revealed that the most important feature of our risk assessment model was phenyllactic acid (Fig. 4A). By analyzing the untargeted metabolomic data from the European MICROBARIA cohort (52), we found that phenyllactic acid negatively correlated with ALT, AST, and gamma-glutamyl transferase (correlation coefficients = -0.35 , -0.45 , and -0.45 ; $P = 0.004$, 0.14, and 0.053; Pearson's correlation adjusted for age, BMI, fasting glucose, and insulin).

SHapley Additive exPlanations (SHAP) (65) analysis also revealed that *Methanobrevibacter* was associated with NAFLD^{-/-}, and *Slackia* was associated with NAFLD^{-/+} (Fig. 4, A and B). These genera were differentially abundant in our two study groups (fig. S2D). Furthermore, 8,11,14-eicosatrienoic acid, hydrocinnamic acid, and oxoglutaric acid are associated with type 2 diabetes, obesity, insulin resistance, and NAFLD (58, 60, 61, 66), and our model revealed similar trends (Fig. 4, A and B).

The feature set contribution was also computed by summing the SHAP values per category. Metabolites were the most important in the model, contributing 44.6% to model performance, followed by

Fig. 3. Predictive performance of machine learning models in the study cohort and diagnostic performance of the final model in external cohorts. (A to C, in blue) Performance of leave-one-out iterative machine learning models discriminating between NAFLD^{-/+} and NAFLD^{+/-} groups using features of the following: (A) metagenomics + metabolome, (B) metagenomics + metabolome + 2 clinical parameters (HDL and fasting insulin), and (C) metagenomics + metabolome + 2 clinical parameters (HDL and fasting insulin) + anthropometrics (BMI and age). (D to G, in purple) Diagnostic performances of a model built based on subsets of the selected features to discriminate between participants who were healthy or had NAFLD in four external cohorts: (D) a Chinese cohort in which NAFLD diagnosis was determined with biopsy, (E) a Chinese cohort in which NAFLD diagnosis was based on MRS, (F) a biopsy-diagnosed European NAFLD cohort, and (G) a biopsy-diagnosed U.S. cirrhosis cohort. (H to J, in peach) Leave-one-out iterative machine learning performance to discriminate between NAFLD^{-/+} and NAFLD^{+/-} groups in models of: (H) FGF21 + BMI clinical model, with and without metagenomics + metabolome features; (I) FLI clinical model, with and without metagenomics + metabolome features; and (J) TyG clinical model, with and without metagenomics + metabolome features. (H to J) Models without metagenomics and metabolome features were trained by logistic regression (dotted lines); models including metagenomics and metabolome features were trained by random forest (solid lines). Confusion matrices in (F) to (H) are from models with metagenomics and metabolome features. The figure colors represent the purpose of the model: blue, model construction; purple, external validation in cohorts of different ethnicity; peach, testing performance of previous clinical models in our cohort. Further details of the overall machine learning analysis framework can be found in fig. S6. auROC, area under the receiver operating characteristics curve; auPRC, area under the precision-recall curve; TPR, true-positive rate; FPR, false-positive rate.

the microbiome and nonmicrobiome features, with contributions of 31.2 and 24.1%, respectively (Fig. 4C).

Dependence plots were built to reveal the nonlinear correlations of features and risk of NAFLD. The optimal thresholds of each feature were identified (fig. S7). We found that high-density lipoprotein (HDL) was associated with NAFLD occurrence after 4.6 years when <1.39 mM, which is close to the diagnostic criteria for metabolic syndrome when HDL was <1.0 mM (male) or <1.3 mM (female) (67). We also examined the dependence plots of microbial metabolite phenylacetic acid, hydrocinnamic acid, and 8,11,14-eicosatrienoic acid (Fig. 4, D to F). Phenylacetic acid was associated with protection against NAFLD at a concentration of >0.25 μ M. The concentration

of 8,11,14-eicosatrienoic acid increased the risk of NAFLD at >51.5 μ M, and hydrocinnamic acid was associated with NAFLD at a concentration of <0.39 μ M. Visual inspection of the dependence plots did not indicate any differences by sex. We converted the features into binary variables (\geq or < thresholds) according to their optimal threshold and found that 12 of 18 features showed significant association with NAFLD progression (chi-square test, $P < 0.05$; table S6). These results demonstrated the importance of including an interpretable machine learning framework, such as SHAP, to provide insights when analyzing microbiome data.

We further examined whether the features of our risk assessment model could be used to classify subjects of the NAFLD^{-/+} group based

Fig. 4. SHAP-based model interpretation. (A) Bar plot of selected features and their contribution in the NAFLD prediction model. Features are in descending order by contribution (also known as importance) in the model. Blue bar, higher value of the feature for association with NAFLD^{-/-}; red bar, higher value of the feature for association with NAFLD^{+/-}. Details of associations are shown in (B) a bee swarm plot in which each point represents a participant ($n=180$). Color indicates the value of the feature, with red higher and blue lower. Negative SHAP value indicates the feature attribution for prediction of NAFLD^{-/-}; Positive SHAP value indicates the feature attribution for prediction of NAFLD^{+/-}. (C) Feature category contribution calculated by summing the SHAP values per set. (D to F) Examples of SHAP dependence plots, showing the effect the feature has on model prediction. Each point represents a participant ($n=180$). Color indicates sex with blue for male and red for female. X axis is the feature value, and y axis is the SHAP value for the feature. The optimal thresholds for features are indicated by the vertical dotted lines.

on different degrees of steatosis. We initially divided the NAFLD^{-/+} group based on their liver fat percentage at the time of diagnosis (4.6 years after enrolment). Subsequently, using the values of the 18 features at baseline, we built a model classifying mild and severe steatosis cases. This new random forest model had an auROC of 0.78 (fig. S8A). Similarly as above, we attempted to confirm the biological relevance of the selected features by testing the diagnostic power of our prospective model in an independent external case-control cohort from the United States (49). Despite the lack of absolute quantification of metabolomic data, our model showed an accuracy of 71.4% to correctly identify severe steatosis cases with only gut microbial and clinical features.

Previous work has demonstrated the value of gut microbiome-based diagnostic tests for advanced fibrosis (68). The participants in our cohort were unlikely to develop advanced fibrosis after 4 years, starting as NAFLD free at baseline. Nevertheless, the prospective design of our study enabled us to explore whether the baseline microbiota is associated with the change or deterioration of fibrosis. Grouping our NAFLD^{-/+} participants by the change of fibrosis 4 (FIB-4) index from 2014 to 2018, we built a new risk assessment model using five gut microbiota functional pathways, classifying subjects by the fibrosis deterioration with an auROC of 0.72 (fig. S8B). In a U.S. case-control cohort (49), the pathway with the highest importance in our model, phosphopantothenate biosynthesis, was significantly higher (zero-inflated Gaussian mixture model, $P < 0.05$) in the cirrhosis group than in non-NAFLD controls. *Methanobrevibacter*, which was the top taxonomic feature in the prospective model, was also significantly lower (zero-inflated Gaussian mixture model, $P < 0.05$) in patients with cirrhosis.

DISCUSSION

NAFLD prevalence has rapidly increased over a short time, especially in China (69). China is projected to have the largest number of liver-related deaths among the most economically developed countries by 2030 (70). Accumulating evidence suggests that the gut microbiome may emerge as an active player in NAFLD development (71). Human studies demonstrated different gut microbiota profiles among individuals with NAFLD and those without, as well as in individuals at different stages of NAFLD (68, 72). In the recently proposed concept of metabolic-associated fatty liver disease (MAFLD) that extends beyond NAFLD (23), gut microbiota is suggested to be a major factor related to the heterogeneous phenotype of MAFLD. In both NAFLD and MAFLD, the disease complexity and heterogeneity may be better resolved by the inclusion of omics technologies that integrate patient clinical phenotypes and molecular phenomics and gut microbial features. This approach has shown its potential in the classification of hepatic (73) and, more recently, extrahepatic diseases including ischemic heart disease (74) and coronary artery disease (75). Both studies of cardiovascular diseases suggested that major alterations of the gut microbiome and metabolome might occur earlier than clinical onset of disease, suggesting the utility of gut microbiota-based risk assessment. A recent prospective study extended cross-sectional evidence and demonstrated that gut microbiota composition is predictive of incident type 2 diabetes after 15.8 years (76). Our study comprehensively characterized the gut microbiome of Chinese participants using stool samples taken 4.6 years before the NAFLD diagnosis and matched controls. We assessed the ability of metagenomic and metabolomic features

as a risk assessment tool of NAFLD occurrence within 4.6 years and developed a random forest machine learning model that distinguished individuals at risk for NAFLD from controls with a performance of 0.80 auROC. The final model consisted of 18 features of mainly bacterial genera, pathways, and metabolites, with two clinical and two anthropometric parameters. Using subsets of those features available in external case-control cohorts also showed good ability (auROC of 0.73 to 0.78) to classify individuals with and without NAFLD, including in cohorts with the biopsy-confirmed present/absence of NAFLD and of different ethnicities, supporting the biological relevance and generalizability of our prospective model.

Diagnosis of NAFLD requires evidence of hepatic steatosis, either by histology or imaging. Liver biopsies have a risk of severe complications, and the sampling procedure may leave some people with NAFLD undiagnosed if they have unevenly distributed histological lesions (13). Steatosis evaluation based on imaging such as MRS, CT, or ultrasonography has limitations in clinical practice such as high price, radiation exposure, and limited sensitivity. Numerous research efforts have searched for other reliable, cost-effective, non-invasive diagnostic approaches, including using features that are clinical (age, gender, diabetes, and BMI), biochemical (aminotransferases, bilirubin, and ferritin), metabolic (glycated hemoglobin, insulin, and HOMA-IR), or lipid (TG and cholesterol) parameters or other markers such as FGF21 and adiponectin (77–79). A few prospective studies have also attempted to predict the development of NAFLD over the long term (19–21). However, the predictive power of these models was evaluated in study groups with unmatched baseline characteristics, which may have led to overestimation of model performance. In our community-based prospective study, these models showed limited performance (auROC in the range of 0.58 to 0.60) when our nested case-control design included matching for gender, age, BMI, and 4-year BMI change. This matching is particularly important for removing confounding effects and to uncover microbiome-related risk factors for NAFLD development, given that obesity is a major risk factor for NAFLD. Our microbiome-based model demonstrated a good performance (auROC of 0.72) for predicting the NAFLD status of NAFLD-free individuals after 4.6 years.

Our study has limitations. The classification of patients into two groups was not based on liver biopsy, which remains the gold standard for NAFLD diagnosis. However, this method is impractical in a community study with thousands of participants, as in our study, and is unethical for participants who do not show any sign of the disease (matched controls). Moreover, according to guidelines from the European Association for the Study of the Liver, European Association for the Study of Diabetes, and European Association for the Study of Obesity, ultrasound is the first-line diagnostic test for NAFLD (36), especially for large-scale screening studies. This diagnostic criterion has been extensively used in previous studies, such as the Rotterdam cohort (80), the Golestan cohort (81), and the Kangbuk Samsung Health Study (82). We note that our cohort is of high quality, with relatively comprehensive indexes acquired in a large population. For example, in the measurement of glucose metabolism, oral glucose tolerance tests were conducted for all participants. This test is usually replaced by fasting glucose or FINS tests in many population-based studies. Second, we could not predict the development of more severe outcomes such as fibrosis because of their low incidence. This was mainly due to the nature of our community-based epidemiological investigation. However, using baseline microbiota, we were able to classify subjects by fibrosis deterioration with an auROC of 0.72.

Furthermore, serum ferritin was not measured in our study, although several studies have indicated its relevance in NAFLD (83–85). Therefore adding ferritin in our prospective model could potentially enhance performance. The predictive power of our prospective model (auROC of 0.80) was an advance compared to existing clinical models (auROCs of 0.58 to 0.60). However, further improvements, for example, integrating additional biochemical parameters, will be necessary for clinical applications. Our metabolic signatures and their taxonomic drivers revealed by our prospective model imply but do not prove causality; thus, additional studies are required to clarify the molecular mechanisms involved in NAFLD development.

Integrating bacterial species and functions in machine learning models for predicting host response to treatment or lifestyle interventions and disease progression has shown great potential (86–89). For NAFLD and its complications, gut microbiota changes can independently predict the risk of short-term hospitalizations (90 days) in patients with cirrhosis with an auROC of 0.83 (90). Elucidating the importance of the gut microbiome as a long-term risk assessment tool in NAFLD is important because of the current limited therapeutic landscape for NAFLD and findings that early detection can substantially improve outcomes for patients with NAFLD (91, 92). Our proof-of-concept study identified a microbiome signature in participants at risk of developing NAFLD in the next 4 years and points to the potential of noninvasive diagnostic tests to complement existing clinical screening tools for NAFLD. Moreover, identifying microbiome signatures also opens a window of opportunities for microbiome-based prophylactic and therapeutic interventions such as the utility of propionic acid as a potent immunomodulatory supplement to multiple sclerosis drugs (93), which is not offered by a clinical predictive model built upon only a few clinical parameters or other features. Evaluation and further improvement of our NAFLD risk assessment model using larger prospective studies that are heterogeneous for ethnicity and lifestyle patterns will increase the model's generalizability and obtain more refined estimations of its accuracy.

MATERIALS AND METHODS

Study design

The aim of this study was to identify potential predictive signatures for early clinical warning of NAFLD and to develop a prognostic risk assessment model for long-term NAFLD development. For this purpose, we conducted a nested case-control study within a 4.6-year prospective study in 2487 Chinese individuals, and we profiled 180 individuals from 1216 NAFLD-free participants at baseline, including 90 that were diagnosed with NAFLD in the follow-up visit (NAFLD^{+/+}), which were matched with 90 controls without NAFLD (NAFLD^{-/-}) by gender, age, BMI, and 4.6-year BMI change. We performed comprehensive metagenomic and metabolomic analyses using stool and serum samples taken at baseline, including taxonomic diversity and profiles at family, genus and species levels, microbial enzymes, metabolic pathways, and metabolites. An interpretable machine learning model integrating baseline microbial signatures was built to predict NAFLD development after 4 years. The biological relevance of selected features in the model to NAFLD development was further validated in external cohorts, including three cohorts with the biopsy-confirmed presence/absence of NAFLD. New models were built for validation, given that some features were not available in the external cohorts. All validation models were trained on our cohort

and tested in the external cohorts. Further materials and methods details are available in the Supplementary Materials.

Study participants

All participants were from the Nicheng Diabetes Screening Project (also called the Shanghai Nicheng Cohort Study) previously described (94, 95). This population-based, prospective study was designed to assess the prevalence, incidence, and factors related to cardiometabolic diseases among adults in Nicheng County, a suburb of Shanghai, China. On the basis of the project, we designed a nested case-control study to explore the potential causal role of the gut microbiome in NAFLD in three randomly selected Nicheng communities (involving 2487 participants). Figure S1 outlines study enrolment. Of 2487 participants, 1216 were identified as not having NAFLD at baseline; among them, 524 completed a follow-up visit 4.6 years after baseline and were screened by ultrasonography. Incident cases of NAFLD ($n = 146$) were identified at the 4.6-year follow-up visit, of which 90 participants were eligible for this study involving gut microbiota, according to the following criteria to exclude participants: existed fatty liver, acute infectious disease, biliary obstructive diseases, alcohol abuse (more than 140 g of ethanol/week for men or 70 g of ethanol/week for women), acute or chronic cholecystitis, acute or chronic viral hepatitis, cirrhosis, diarrhea, known hyperthyroidism or hypothyroidism, chronic renal insufficiency, heart failure, presence of cancer, pregnancy, stroke in acute phase, receipt of any antibiotic treatment within 2 weeks or receipt of any probiotic or prebiotic within 1 week before sample collection, and suffering from chronic or acute gastrointestinal diseases (including diarrhea, gastrointestinal infection, and inflammatory bowel disease) in recent 1 month before sample collection. Controls ($n = 90$ for a case-control ratio of 1:1) were chosen from the remaining participants who did not develop NAFLD by the follow-up visit. To control for the risk profiles in patients who developed NAFLD and those who did not, controls were matched for age (± 3 years), sex (male and female), BMI (± 3 kg/m²) at both baseline and follow-up, and BMI change (± 0.5 kg/m²). The study was approved by the ethics committee of the Shanghai Sixth People's Hospital (approval no: 2014-27), following the principles of the Declaration of Helsinki. Written informed consent was obtained from all participants.

Evaluating the diagnostic ability of the model in external cohorts

To our knowledge, no similar studies have conducted long-term follow-up of NAFLD development in healthy individuals using a combination of gut metagenome, metabolome, and clinical features as a risk assessment tool. Thus, we were unable to test our prospective model directly in an external cohort. Instead, we used external case-control cohorts to examine the ability of our final prognostic model to classify correctly NAFLD and healthy participants. Four cohorts were used, including two cohorts of Chinese: (i) 78 patients with NAFLD and 10 controls without NAFLD, as diagnosed with biopsy (BioProject ID: PRJNA732131), and (ii) 111 MRS-diagnosed NAFLD patients and 8 controls (BioProject IDs: PRJNA703757 and PRJNA414688); and two biopsy-diagnosed cohorts of other ethnicity: (iii) a European cohort of 46 patients with NAFLD and 10 controls (54) and (iv) a U.S. cohort of 26 cirrhosis patients and 54 controls (49). For further additional data (e.g., anthropometric and/or available clinical data) for the two Chinese validation cohorts besides grouping information, please contact the corresponding author.

Because some selected features included in the final model were not available in the external cohorts, we were unable to test our model directly. Instead, we built a new prognostic model based on the NAFLD^{-/+} and NAFLD^{-/-} groups using a subset of the 18 selected features that were available in the external cohorts. In the model for the two Chinese cohorts and the European cohort, 9 of the 18 selected features were used: two genera, three pathways, two anthropometric parameters, and two noninvasive clinical metadata; whereas 7 of the 18 selected features were used in the model for the U.S. cohort: two genera, one pathway, two anthropometric parameters, and two noninvasive clinical metadata. Performances of models, including ROC curves, precision-recall curves, and confusion matrices (generated with the optimal probability cutoff of the ROC curve), were produced by applying the model to the unseen external cohort data.

Statistical analysis

Statistical analyses of clinical data were performed with SAS version 9.4 (SAS Institute Inc.). Normally distributed data were expressed as means \pm SD. Data that were not normally distributed, as determined using the Kolmogorov-Smirnov test, were logarithmically transformed before analysis and expressed as median with lower and upper quartiles. Student's *t* test and chi-square tests were used to assess differences between two groups for continuous and categorical variables, respectively. In addition, analysis of covariance was used for continuous variables to assess the difference between the two groups after adjusting for HOMA-IR.

Metagenomic data, including taxonomy and functional data, and metabolomic data were analyzed in R software version 3.6.3. Metagenomic data were analyzed with the zero-inflated Gaussian mixture model, using the function fitZig from R package metagenomeSeq (96) with the default settings; metabolomic data were analyzed using the generalized linear model with inverse gamma distribution. Wilcoxon rank-sum tests were used to test for significant differences in alpha diversity. PERMANOVA was used to analyze beta diversity with adonis function from R package vegan. A Mantel test, implemented in mantel from R package vegan, using Spearman's correlation coefficient was used to analyze the associations between microbiome and metabolites. Bray-Curtis dissimilarity matrices based on taxonomic relative abundance and Euclidean dissimilarity matrix for each metabolite were computed to perform this test. The auROCs of different models were compared with the DeLong test, using the roc.test function from R package pROC (97). Data were considered statistically significant at *P* value < 0.05. The Benjamini-Hochberg procedure was applied to calculate the FDR to adjust *P* values for multiple hypothesis testing.

DISCUSSION

The gut microbiome is considered a key element contributing to the regulation of human health and disease, being associated with the development and severity of numerous highly prevalent and chronic diseases (Thomas et al. 2017). Through the different manuscripts of this thesis, I have provided evidence that the human body together with its microbiome forms a unity of life or holobiont indispensable for the well-functioning of the organism.

During my Ph.D., I have applied state-of-the-art bioinformatics and statistical analyses to better understand and to give new insights into the human gut bacteriome and mycobiome and their implication in non-alcoholic fatty liver disease (NAFLD) progression. In addition, the potential of the gut microbiome to develop new clinical tools was also explored by applying novel machine learning approaches to metagenomic data. In this section I am going to further discuss the following five topics:

- Importance of confounders in microbiome-based data analyses (**manuscripts I, II, III, and IV**)
- Using metagenomics and metabolomics analyses to investigate potential therapies and diagnostic strategies for NAFLD (**manuscripts I, II, and IV**)
- Bioinformatic and machine learning approaches allowed the development of a microbiome-based stratification model (**manuscript II**)
- Limitations in mycobiome analyses (**manuscript III**)
- Synthesis of the four studies comprising this dissertation (**manuscripts I, II, III, and IV**)

Table 1 | Summary table of the manuscripts that comprise this dissertation.

Manuscript	Title
I	Resistant starch decreases intrahepatic triglycerides in patients with NAFLD via gut microbiome alterations
II	Identification of robust and generalizable biomarkers for microbiome-based stratification in lifestyle interventions
III	Genetic variation in IL-17A regulation and mycobiome dysbiosis contribute to non-alcoholic fatty liver disease
IV	Risk assessment with gut microbiome and metabolite markers in NAFLD development

1. Importance of confounders in microbiome-based data analyses

The gut microbiome is a complex ecosystem exposed to numerous covariates and confounding variables (e.g., age, gender, BMI, antibiotics, diet, geography, etc.) (Hasan and Yang 2019). Therefore, the use of analytic approaches to address confounding is needed to obtain more reliable statistical associations to better evaluate the relationship between gut microbiome and disease.

Previous investigations have shown age to affect the gut microbial composition (Odamaki et al. 2016; Ghosh et al. 2020; Wilmanski et al. 2021). Elderly subjects have been found to have distinct gut microbial community characteristics compared to young/middle-aged individuals (Ghosh et al. 2020). In addition, gender has also been mentioned as an important variable affecting the gut microbiome, and it has been suggested that dysbiosis may drive sex differences in the progression of some diseases (Haro et al. 2016; Ahmed and Spence 2021). Haro et al. found that gender differences in the gut microbiome may be influenced by the grade of obesity. Ethnicity is another important variable to consider in microbiome analyses. Different investigations have explored the influence of ethnicity on the gut microbiota, and differences in the diversity of the microbial composition and in the abundances of some gut microbes have been shown between different ethnicities (Deschasaux et al. 2018; Dwiyanto et al. 2021; Boulund et al. 2022). Diet is also an important factor to take into account in microbiome studies as some foods may produce significant alterations in the gut microbial community (Johnson et al. 2019). In addition, medication is also a major confounder when analyzing the gut microbiome, as some medications including antibiotics and non-antibiotics drugs may alter the microbial community in the gut (Weersma et al. 2020). For example, commonly used drugs such as proton pump inhibitors (drugs used to treat acid-related disorders), laxatives (drugs to treat constipation), and metformin (oral blood glucose-lowering compound used in the treatment of T2D) have been shown to influence gut microbiome composition and function (Weersma et al. 2020). Antibiotics also have a drastic effect on the gut microbiota community (Taur et al. 2018; Palleja et al. 2018; Gutierrez et al. 2020; Seelbinder et al. 2020; Ramirez et al. 2020). Availability of the medication patient history during and some months before the clinical trial allows us to determine, when designing the analysis strategy, the most appropriate statistical analysis accounting for these drugs when convenient. Therefore, considering and accounting for these confounders in microbiome-based analyses has become a recommended practice in the last years (Gao et al. 2018; Zhong et al. 2019; Jie et al. 2021; Zuo et al. 2022).

In different projects that comprise this dissertation (**manuscripts I, III, and IV**), I made use of statistical approaches that allowed accounting for gut microbiome influential variables such as age, gender, and BMI, as they influence the statistical results when analyzing the gut microbiome community (Ghosh et al. 2020; Tierney et al. 2022). For each manuscript, apart from the main variables of age, gender, and BMI; the most appropriate confounders were chosen depending on the cohort, research question, and objectives of each project. In **manuscript III**, where we investigated changes in the fungal community in NAFLD subjects, our NAFLD cohort was free of antibiotic intake for at least 6 months

before the sample collection. A recent study showed that antibiotics might have a long-term influence on the human mycobiome compared to the bacterial community (Seelbinder et al. 2020). Therefore, I investigated if antibiotics had a noticeable long-term effect in the fungal community of our cohort and I found a significant impact in alpha diversity between antibiotic-free and the individuals that took antibiotics more than six months before the sample collection in the NASH group. Knowing this, in the analyses performed with the full cohort, the antibiotic intake was considered as a confounder. This allowed me to keep the full cohort of samples to perform the analyses, without removing samples considering the antibiotic intake. In addition, analyses were also performed in the sub-cohort of antibiotic-free samples and the same results were found providing confident and reliable conclusions.

On the other side, accounting for specific confounders may be useful when investigating a certain disease in order to adjust for the major confounders linked to some conditions that may affect the analyses. To determine the major confounders that are of interest to be included, it is important to understand the disease pathogenesis and its implication with other complications. NAFLD is associated with metabolic and cardiovascular disorders such as T2D, obesity, and hypertension (Kolodziejczyk et al. 2019). Therefore, in the NAFLD-related projects of this dissertation (**manuscripts I, III, and IV**) differential abundance and correlation analyses were performed accounting for obesity- and diabetes- related parameters (e.g., BMI, VFA, SFA, adipo-IR or HOMA-IR) when appropriate. Adjusting for obesity- and diabetes-related variables allowed us to obtain conclusions linked directly with NAFLD progression and not to these conditions. In addition, in **manuscript I** where we explored RS supplementation as a potential microbiota-directed food intervention, we accounted for weight loss when we investigated the clinical changes that underwent the RS intervention group compared to the control group. We found that the amelioration of the disease progression in the RS intervention group, showed by a reduction of intrahepatic triglyceride content (IHTC, our primary outcome) and an improvement in liver injury and related metabolic disorders, was independent of the weight loss. One limitation when performing these types of analyses adjusting for confounders, is the possibility of having numerous missing values in the confounder variables. Missing or incomplete data on the confounding factors may lead to a result bias (Lin and Chen 2014). In addition, the available functions and tools to adjust for confounding do not usually allow to provide the factors for the adjustment with missing values. Therefore, missing samples need to be removed or methods for data imputation should be used to perform the analyses.

Another fact that I considered during my research to have more generalizable and confident conclusions is the validation of the results in different population cohorts when convenient, and for example in cohorts from different ethnicities. Nowadays, this task has become easier to put into practice thanks to the large amount of openly available data. In **manuscripts I and IV**, we investigated the role of the gut microbiome in two Chinese NAFLD cohorts. In **manuscript I**, I also explored the abundance of the identified detrimental species *B. stercoris* in two external cohorts, one Chinese and one European, confirming our results in different population cohorts including different ethnicities. In **manuscript IV**, we developed an early NAFLD detection machine learning model and the performance of the final model was also validated in several external case-control cohorts from Asia, the United States, and Europe. Apart from the non-invasive risk assessment model for NAFLD development, a model to classify different degrees of steatosis and a

model to predict the fibrosis-4 (FIB-4) index change four years later were built and validated in the external cohorts. Lastly, in **manuscript II**, different cohorts with Asian and Caucasian ethnicities were used to build the microbiome-based stratification model for lifestyle interventions, and the final model was validated in two external cohorts with Caucasian and American ethnicities. Therefore, the microbiome-based machine learning models developed in **manuscripts II and IV** were validated in different cohorts including different ethnicities obtaining a good model performance supporting the biological relevance and generalizability of the models and the biomarkers identified.

In conclusion, the different manuscripts that comprise this dissertation have shown the importance of the covariates in microbiome-related data analysis to obtain generalizable and more comprehensive conclusions. Taking into consideration microbiome-related cofounder factors and including statistical approaches that allow accounting for confounders in microbiome-based studies, helps and improves the identification of disease-specific microbiome alterations, and it is encouraged to be applied for further microbiome-based studies. In addition, validation of the results in different population cohorts, when possible, is suggested to obtain more confident and generalizable results.

2. Using metagenomics and metabolomics analyses to investigate potential therapies and diagnostic strategies for NAFLD

Previous research has investigated the beneficial effects of resistant starch (RS) supplementation on host health (Zhu et al. 2022). One of the advantages of RS is that it is a relatively simple and inexpensive dietary strategy. RS has been found to decrease fat accumulation by improving insulin sensitivity and maintaining lipid metabolic homeostasis (Zhang et al. 2015; Maier et al. 2017). In a previous study, RS significantly improved insulin and low-density lipoprotein (LDL) in obese individuals (Eshghi et al. 2019). RS also showed a significant reduction of liver steatosis and in the serum levels of ALT, TG, and HOMA-IR in NAFLD mice (Shou et al. 2021). However, RS supplementation has never been explored in a clinical study on NAFLD patients. Therefore, in **manuscript I**, I made use of bioinformatic and statistical techniques in order to investigate RS supplementation as a potential microbiota-directed foods (MDFs) therapy to treat NAFLD. We performed a randomized clinical trial where we identified RS as having a beneficial effect with a reduction of the IHTC independently of weight loss in the intervention group. RS also reduced body weight, body fat, abdominal fat, liver enzymes, liver profiles, fasting insulin, insulin resistance, and serum fibroblast growth factor (FGF21). Combining shotgun metagenomics sequencing and targeted metabolomic profiling we discovered that improvements produced by RS intervention may lead to beneficial changes in the gut microbiota composition and the metabolic profile. We found decreased levels of microbial metabolic products, especially the AAs pool and BCAAs levels. Previous studies have demonstrated an increase in the circulating levels of BCAAs (leucine, isoleucine, and valine) in NAFLD and NASH (Kalhan et al. 2011; Goffredo et al. 2017; Gaggini et al. 2018). Correlation analysis showed BCAAs levels to be significantly positively correlated with IHTC, ALT, AST, and GGT. In addition, the correlation with IHTC was found to be

independent of body weight and insulin resistance, suggesting a direct influence on BCAAs with NAFLD pathogenesis. We deeper investigated the effect of RS on the microbial composition, and we identified a significantly reduced abundance of *Bacteroides stercoris*, a species that was also correlated with IHTC, ALT, and AST levels when controlling for age, gender, HOMA-IR, and obesity-related parameters. This finding suggested that the effect of *B. stercoris* on NAFLD aggravation was independent of body weight and insulin resistance.

The availability of WGS data allowed us to profile the functional potential of the gut microbiota community. We found that the phenotypic alleviation of NAFLD may be potentially linked to a reduction in the intervention group of lipopolysaccharide (LPS) biosynthesis and export. Previous studies have associated an increase in LPS production with NAFLD and the progression of hepatic steatosis (Soares et al. 2010; Fukunishi et al. 2014; Carpino et al. 2020).

In **manuscript I**, a sophisticated computational framework was applied to integrate microbial species, functions, and host phenotypes. From this comprehensive analysis, *B. stercoris* was identified to contribute to the correlations of several BCAAs biosynthesis modules and the clinical phenotypes IHTC and FGF21. To date, no research has been done investigating the effect of *B. stercoris* on the aggravation of diseases. In this project, we validated the positive association of *B. stercoris* with NAFLD in mice by conducting a monocolonization study to confirm the NAFLD-promoting effect of *B. stercoris* and to explore the possible mechanisms involved.

Bioinformatic analyses performed suggested *B. stercoris* as a good candidate to investigate its role in NAFLD aggravation and it was validated in different experimental studies by our collaborators. Of note, experiments were carried out using a specific *B. stercoris* strain, despite the fact that the taxonomic profiling only reached the species level. In some cases, subtle genetic differences between strains within a single bacterial species can have profound impacts to induce different behaviors (Ghazi et al. 2022). For example, *Escherichia coli* strains have been shown to be commensal, pathogenic, host-associated, or environmental (Leimbach et al. 2013). Yet methods for strain-level assignment are insufficient, therefore numerous efforts are being done to improve and develop tools for more precise strain-level analyses. Especially, the main challenges consist of dealing with reference databases including highly similar reference strain genomes and the possibility of having multiple strains under one species in a sample (Liao et al. 2022). Advances in metagenomic strain-level population genomics will allow researchers to perform more accurate and high-resolution microbiome analyses.

The results presented up to here demonstrate the role of a single species, namely *B. stercoris*, in facilitating the progression of NAFLD through BCAA production. These results have helped to understand some mechanisms involved in the disease pathology. However, NAFLD is a complex disease caused by multiple mechanisms and not by a single species, but rather by, most probably, broad microbiome changes. To provide evidence about the causal role of whole microbiota changes in NAFLD, in **manuscript I** we performed FMT in mice fed with a Western diet. Previous mice studies have also explored gut microbiota's role in NAFLD through FMT (García-Lezana et al. 2018; Xue et al. 2019; Shou et al. 2021). Our study showed that FMT of RS-altered microbiota profile alleviates NAFLD by, among other findings, reducing hepatic steatosis, improving gut barrier

integrity, promoting the expression of lipolysis, and reducing inflammation-related genes, suggesting a causal role of gut microbiota in attenuating NAFLD.

To help to understand the implication of not only bacteria but also the fungal community in NAFLD pathogenesis, in **manuscript III** we performed genotyping and mycobiome analyses in a NAFLD cohort and investigated associations between genetic variations in antifungal immunity and fungal changes in NAFLD. A previous study showed an increase in the frequency of IL-17-producing cells among intrahepatic CD4⁺ T cells and a higher Th17/resting regulatory T cells (rTreg) ratio in peripheral blood in NAFLD progression to NASH (Rau et al. 2016). From the genotyping and bioinformatics analyses, we identified an association between the IL-17A rs2275913 variant and fibrosis severity that is accompanied by mycobiome dysbiosis, where we found increased abundances of the *Candida* CTG-clade in patients with advanced fibrosis. Previous studies have found an increase of *Candida* CTG-clade species such as *Candida albicans* and *Debaryomyces hansenii*, that were found higher in liver- and gastrointestinal-related diseases (Jain et al. 2021; Hartmann et al. 2021; Li et al. 2022b). In **manuscript III**, *ex vivo* T-cell stimulation assay performed by our collaborators demonstrated elevated IL-17A levels in response to *D. hansenii* and *C. albicans* lysates in rs2275913 minor allele variant, suggesting a Th17-stimulating potential. Together with the elevated *Candida* CTG-clade abundance in NAFLD patients identified from the bioinformatic analyses, our results suggest a combinatory effect of dysregulated antifungal immunity and an imbalance in *Candida* CTG-clade species on fibrosis development in patients with NASH. After investigating the fungal changes in our NAFLD cohort, I performed community network analysis that allowed the integration of bacterial and fungal genera and the identification of one subcommunity module containing *Candida* CTG-clade together with one more fungal and nine bacterial genera, that was found to be associated with NAFLD progression, suggesting multiple microbial factors contributing to NAFLD.

Trying to address the current challenge of finding new clinically reliable and cost-effective strategies for diagnosis and early detection of NAFLD mentioned in the introduction section 2.1, in **manuscript IV**, the potential value of the gut microbiome in NAFLD diagnosis was explored. The use of shotgun metagenomics and targeted metabolomics combined with clinical information allowed the development of a machine learning model able to early predict NAFLD development. A recent study has shown the predictive capacity of the gut microbiome for incident liver diseases (Liu et al. 2022). Liu et al. showed that adding microbiome information to conventional risk factors improved the model performance that successfully predicted the development of liver disease 15 years later. In relation to NAFLD, up to now, some studies have built predictive models for early detection of NAFLD using clinical biomarkers such as fatty liver index (FLI), FGF21, BMI, or TG, and glucose index (TyG) (Li et al. 2013; Zheng et al. 2018; Motamed et al. 2020). In **manuscript IV**, we characterized the gut microbiome of the cohort and we found at the baseline differences in the microbiome signature and metabolic shifts in subjects that will develop NAFLD compared to controls. Novel machine learning approaches were used to build a non-invasive risk assessment model to predict NAFLD progression and to identify microbial signatures in participants at risk of developing NAFLD in the next four and a half years. Feature selection approaches identified 18 features including bacterial genera,

pathways, metabolites, and clinical parameters; as potential early NAFLD biomarkers having a relevant role in early NAFLD detection. In addition, incorporating the final model microbiome features into previous clinical models (Li et al. 2013; Zheng et al. 2018; Motamed et al. 2020), produced significant improvements demonstrating the potential of the microbial community for early NAFLD detection. Finally, to further explore the relevance of the selected features, a new model to classify mild or severe steatosis was built using the 18 selected features obtaining a good model performance.

In conclusion, the metagenomic and metabolomic approaches used in this thesis have allowed a better understanding of the implication of the gut microbiome in NAFLD development and progression. Comprehensive analyses and application of bioinformatic pipelines have helped to identify microbial biomarkers and to validate the vital role of the bacteriome, mycobiome, and metabolome in NAFLD pathogenesis. These new findings may direct the development of new microbiome-based therapies and diagnostic strategies for NAFLD, that will help to improve the population's quality of life and to reduce the healthcare cost for NAFLD management.

3. Bioinformatic and machine learning approaches allowed the development of a microbiome-based stratification model

In the last years, the application of machine learning approaches in microbiome-related studies has been widely applied. Machine learning has become a powerful tool to identify microbiome signatures and microbial biomarkers. It is also employed in model development for diagnostics, biotherapeutic selection, patient stratification, and early disease detection (Richens et al. 2020; Spiga et al. 2021; Huang et al. 2021). In this thesis, machine learning approaches were applied in **manuscripts II and IV** to develop models for microbiome-based stratification and early NAFLD detection respectively. In this section, I am going to focus on **manuscript II** where I applied machine learning approaches to build a microbiome-based patient stratification model.

Nowadays novel microbiome-targeted interventions that aim to target and alter the gut microbial community to improve the host health are widely investigated and applied (e.g., **manuscript I**). However, clinical trials have demonstrated that there are large interindividual differences in the treatment response and some of these differences may depend on subject-specific gut microbial composition (Cotillard et al. 2013; Korpela et al. 2014; Tap et al. 2015). The gut microbiota is resistant to changes and some microbiome-targeted interventions are not going to affect the microbial composition of some individuals. Knowing in advance if a microbiome community will react to specific lifestyle components may help to optimize personalized lifestyle approaches. Therefore, in **manuscript II**, we aimed to identify microbial biomarkers among the gut microbial community associated with the degree of change in the microbiome structure and develop a machine learning model able to predict microbial responsiveness.

In order to build the stratification model, we first applied bioinformatic analyses to investigate the resistance potential of the gut microbial ecosystem of an individual using a stability metric called intraclass correlation coefficient (ICC), and established a criterion for

distinguishing significant changes from natural fluctuations of the gut microbiota community. Differentially abundant analysis was performed to identify highly abundant species in the individuals that showed minor impact on the microbial's community structure also named as non-responders, and in the individuals that showed significant changes in the microbial community in response to lifestyle interventions or responders. From the differentially abundant and microbiome stability analyses we identified 3 species, *Prevotella copri*, *Bacteroides stercoris*, and *Bacteroides vulgatus*, to be potential biomarkers of microbiome resistance. We also explored the species highly abundant in responders and a total of 38 species were identified. Interestingly, most of these species were correlated with at least one amino acid biosynthesis pathway. We further investigated amino acid biosynthesis-related pathways and explored the top species that contributed to these functions. Network analysis performed showed differences between responders' and non-responders' community networks. We identified in the responders network that amino acid auxotroph species suggested by Yu et al. study (Yu et al. 2022) were also correlated with amino acid-related KOs when integrating the functional profile into the network. Previous studies have shown that metabolic cross-feeding is a crucial process involved in the development and composition of the microbial community (Henriques et al. 2020; Lopez and Wingreen 2021). In addition, Mee et al. observed that microbial genomes for amino acid biosynthesis are absent in a substantial proportion of all bacteria (Mee and Wang 2012), therefore, amino acid auxotrophy may have an important role in promoting cooperative interactions between different bacteria in the microbiome (Mee et al. 2014).

The different analyses performed in the first part of the study suggested that amino acid biosynthesis has an important role in microbiome dynamics; plus, comprehensive analyses identified signature species in responders' and non-responders' microbial profiles that may serve as potential microbial biomarkers of the microbiome's resistance to lifestyle interventions. These differences found at the baseline microbial community between responders and non-responders suggested that machine learning approaches may be able to successfully predict the gut microbiome responsiveness to a lifestyle intervention using the gut microbial profile before starting the intervention.

Previous studies have developed machine learning models that predict host phenotype changes such as insulin resistance (Liu et al. 2020), fat change (Jian et al. 2022), or significant weight loss (Dong et al. 2021) in response to lifestyle interventions using the microbial community at the baseline. However, few studies have focused on investigating microbiome resistance in response to lifestyle interventions, with only one recent study that proposed a method for preliminary assessment of the microbiome response using amplicon data (Klimenko et al. 2022).

In **manuscript II**, I made use of gradient boosting, a widely used method for regression and classification, to build a model that predicts the microbiome resistance to lifestyle interventions using the microbial composition of the individuals before they start the intervention. Gradient boosting is a popular machine learning algorithm that has been used across different domains including metagenomics (Ryan et al. 2020; Liu et al. 2022). In this project, I investigated how different microbiome-related data (species, genera, and pathways) were able to predict the microbiome resistance to change after lifestyle interventions. A final taxonomic-based model was built achieving a good performance with

an AUC up to 0.86 in two validation population cohorts from different ethnicities. Recursive feature elimination was used as a feature selection method to subset the top 30 features used by the model. A total of 12 genera and 18 species contributing to the prediction of microbiome resistance to interventions were selected from which 19 were identified in previous analyses of the study as associated with microbiome responsiveness, confirming the relevance of these taxa in the microbiome dynamics in response to lifestyle interventions. Therefore, the predictive model built may potentially serve as an initial step to personalized lifestyle intervention therapies by applying a microbiome-based stratification strategy.

Despite our promising results, we are aware that a larger number of samples would allow us to perform more advanced machine learning algorithms, such as deep learning. In this sense, the availability of more longitudinal cohorts with clinical and biochemical characterization would be beneficial for future studies. In addition, the integration of clinical and biochemical profiles may help to build more precise and personalized models.

In conclusion, this study demonstrated that there are differences in the baseline microbial community signatures that characterize the microbiome's resistance to lifestyle interventions, and we present a machine learning model that predicts the microbiome resistance to interventions using the baseline microbiome composition. The application of machine learning approaches is helping to improve the design of personalized lifestyle approaches and to develop new models for therapeutic strategies. Future approaches combining stratification by host phenotype and by gut microbial characterization will optimize the intervention response of individual patients, achieving a greater success in treating patients.

4. Limitations in mycobiome analyses

Even though the mycobiome constitutes only a small proportion of the microbes living in the gastrointestinal tract, the potential role of the fungal community in the gut is increasingly recognized (Huseyin et al. 2017). Yet, the gut mycobiome remains underinvestigated, being bacteria the main focus of study in the last decades. Therefore, mycobiome data analyses are still limited remaining one step behind compared to bacteriome analyses (Thielemann et al. 2022). Apart from challenges in the sample collection, sample processing, and storage; several limitations still arise concerning the bioinformatic analyses including the lack of reference databases, standardization procedures, and analysis pipelines or tools.

The availability of well-curated and high-quality databases is needed for comprehensive and more robust taxonomic classification, and fungal databases are often being updated (Lücking et al. 2020). The choice of the database has been shown to clearly impact the study results with considerable differences in the community compositions (Huseyin et al. 2017; Thielemann et al. 2022). The curation of databases and fungal profiling tools need to deal with the complexity of the fungal taxonomy and the sparse databases. Due to the complex fungal taxonomy, in **manuscript III**, fungi were grouped according to genus except for the characterization of *Candida*. *Candida* is a polyphyletic genus comprising a large variety of phylogenetically distant species, and to account for this, we

grouped it in the *Candida* CTG-clade. This clade belongs to the order *Saccharomycetales* and clusters the *Candida* spp. characterized by an alternative decoding of the CTG codon leading to a serine amino acid instead of the canonical leucine (Mühlhausen and Kollmar 2014). Some of the species belonging to this clade are *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *Debaryomyces hansenii* (formerly known as *C. famata*). However, other species are distantly related to *Candida* CTG-clade and were partially renamed and regrouped in other genera, for example, *Nakaseomyces glabrata* (commonly known as *Candida glabrata*) and *Kluyveromyces marxianus* (formerly *Candida kefir*) (Borman and Johnson 2020).

The choice of the profiling strategy and the primer may influence the analysis results. Nuclear ribosomal DNA internal transcribed spacer (ITS) has been consensually selected as the formal barcode to assess the fungal composition as this region can amplify the fungal rDNA from the majority of the species (Huseyin et al. 2017). High throughput sequencing strategies focused on two different ITS subloci that are separated by the conserved 5.8S region, the ITS1 and ITS2 regions, however, it is still not clear which of them has the best taxonomic resolution (Yang et al. 2018). In addition, the amplicon strategy used may influence the study outcome due to different fungal taxonomic identification (Monard et al. 2013; Yang et al. 2018; Frau et al. 2019). In **manuscript III**, ITS1 data was used to assess the fungal profile of our NAFLD cohort. Even though ITS2 may have slightly different taxonomic identification, our results go in line with the only previous NAFLD mycobiome study where they used a different primer strategy (ITS2). Therefore, primer bias seems not to have a major influence on the results for overall highly abundant fungal species, despite the fact that previous research has reported ITS1 probably lead to missing species detection from Basidiomycetes phylum (i.e. *Malassezia* and *Cryptococcus*) (Frau et al. 2019). In addition, amplicon sequencing strategies remain to be improved. A study investigating the identification of Basidiomycota species using different primer strategies showed that, neither the complete ITS region nor the sub-regions successfully identified 11 of the 113 Basidiomycota genera (Badotti et al. 2017). Amplicon sequencing has been shown to be helpful for identifying low-abundance fungi, even though it also has some disadvantages as it is subject to selective primer bias or lower taxonomic resolution (Tiew et al. 2020). An alternative is the use of whole-genome shotgun (WGS) metagenomics to study the mycobiome. Different from amplicon sequencing, WGS metagenomics sequences the total DNA from a given sample. However, the availability of tools to characterize the fungal community based on metagenomic reads is almost inexistent. The low abundance of fungi relative to bacterial DNA across a variety of human samples is a challenge for WGS mycobiome profiling. High sequencing depth that goes together with high cost is likely required to determine the fungal composition using WGS metagenomics (Tiew et al. 2020). Much work remains to improve and develop new strategies and protocols for more accurate and sensitive fungal WGS metagenomic profiling.

Finally, more efforts to develop standardized protocols need to be done for fungi. For example, studies have found that the DNA extraction method influences the microbial community obtained (Sui et al. 2020). The impact has been shown to be lower when extracting bacterial DNA, as most of the protocols have been optimized for bacteria, leading to more biased results for other microbes such as fungi (Leigh Greathouse et al. 2019).

Therefore, more investigation is required to evaluate optimal DNA extraction methods and protocols to study fungal communities.

In conclusion, knowledge about the gut mycobiome and how it affects human health and disease is still limited, and new advances and research need to be done in this field. The development of novel tools, standardized protocols, and more complete and curated databases is crucial for achieving more comprehensive mycobiome analyses. Only one previous study together with **manuscript III** has investigated the fungal community in NAFLD development and has demonstrated an important role of the mycobiome in NAFLD progression. Therefore, more studies are required to deeper elucidate the fungal role and its link with bacterial changes in NAFLD.

5. Synthesis of the four studies comprising my dissertation

Numerous studies have found that different types of environmental and lifestyle factors have a clear impact on the gut microbiome of individuals. An important gut microbiome modulator is diet, which has a lot of potential for developing microbiome-based therapies. Consequently, much research has focused on understanding how different types of foods modulate the gut microbiome. For instance, Barone et al. conducted a study demonstrating that a Mediterranean diet promotes a gut microbiome composition associated with health benefits, while a high-fat Western diet leads to gut microbiome alterations with negative implications for metabolic health, including a greater relative abundance of asaccharolytic bacteria as well as of fat- and bile-loving microorganisms (Barone et al. 2019). Ketogenic diet was also found to produce changes in the gut microbial composition associated with an improvement of metabolic health in different diseases including epilepsy, obesity, and dyslipidemia (Attaye et al. 2022). In this dissertation, my manuscript published in Cell Metabolism (**manuscript I, Ni et al. in press**) investigated the potential use of RS as microbiome-directed food to treat NAFLD. In this study, we found that RS supplementation modulates the gut microbiome composition, and possible mediators related to the beneficial effects of RS were evaluated. However, as demonstrated in my publication in Microbiome (**manuscript II, Chen et al. 2023**), each individual's microbiome community response is different and predictable. The ML model that I developed in this study can be used for patient stratification in dietary studies. Therefore, if I had to repeat **manuscript I** study, besides the randomization based on age, gender, and other factors, I could use this ML model to stratify patients including the same proportion of individuals with resistant and flexible gut microbiomes in the two groups.

Apart from the use of machine learning for patient stratification, this novel discipline has a variety of applications in the microbiome field including phenotypic prediction, biomarker discovery, and treatment outcome evaluation among others (Li et al. 2022a). For instance, Heshiki et al. developed a ML model that successfully predicts cancer treatment output using the microbiome information prior to therapy initiation (Heshiki et al. 2020). Another study by Chen et al. constructed a highly accurate age prediction model using gut microbiome data (Chen et al. 2022). My publication in Science Translational Medicine (**manuscript IV, Leung et al. 2022**) presents, for the first time, a microbiome-based

prognostic model for NAFLD. This model incorporates clinical data, metabolites, and gut bacteria community information. However, as demonstrated in my collaborative manuscript with the University of Würzburg (**manuscript III**), not only bacteria but also fungi are playing an important role in the development of NAFLD. Taking into consideration the importance of the fungal community in NAFLD and the recent development of new methods for fungal identification using shotgun metagenomics data (Xie and Manichanh 2022; Narunsky-Haziza et al. 2022; Salem-Bango et al. 2023), it would be very interesting to repeat **manuscript IV** study incorporating the fungal profile in the model. In this way, it would be possible to evaluate the prognostic power and potential of the fungal composition for NAFLD prognosis

DECLARATION

I, Sara Leal Siliceo, as a doctoral student, hereby confirm that:

- I am familiar with the valid doctoral examination regulations.
- I produced this doctoral thesis myself, I neither used any text passages from third parties nor their own previous final theses without citing them.
- I cited the tools, personal information, and sources having been used in this thesis.
- I provide the names of the persons who assisted the applicant in selecting and analyzing materials and supported them in writing the manuscript.
- I did not receive any assistance from specialized consultants and that any third party did not receive either direct or indirect financial benefits from me for the work connected to the doctoral thesis submission.
- I have not already submitted the doctoral thesis project as my final thesis for a state examination or other scientific examination.
- I did not submit the same, a substantially similar, or another scientific paper to any other institution of higher education or to any other faculty.

Place, date

Sara Leal Siliceo

ACKNOWLEDGMENTS

Firstly, special thanks to my supervisor Prof. Dr. Gianni Panagiotou for his guidance, encouragement, and valuable insights. His support and supervision helped me to have the right direction for my research and to develop my career. I also truly appreciate the guidance and technical support during these four years from Dr. Yueqiong Ni.

I would also like to express my sincere gratitude to my colleagues and friends from the SBI group who have supported me throughout the journey of completing this dissertation and make me also enjoy my time in Jena during these four years.

Thanks to my salseros friends from Jena for giving me enjoyable and funny memories.

Thanks also to all my friends from Spain who always supported me from the distance.

Last but not least, I would like to thank all my family who gave me love and helped me during this journey. Special thanks to my parents, sister, and granny. Truly thanks to my love Alejandro that always encourages and supports my dreams.

CURRICULUM VITAE

Personal Details

Name: Sara Leal Siliceo
Date and place of birth: 06.07.1994, Madrid, Spain
ORCID: 0000-0002-9076-3962

Education

2019 – present

Doctor of Philosophy (Ph.D.)
Faculty of Biological Sciences, Friedrich Schiller University, Jena, Germany

2017 – 2018

M.Sc. in Bioinformatics and Computational Biology
Autonoma University of Madrid, Higher Polytechnic University College, Madrid, Spain

2012 – 2016

B.Sc. in Biomedical Engineering
Technical University of Madrid, Higher Technical School of Telecommunication Engineering and Center for Biomedical Technology, Madrid, Spain

Scholarships

2019 – 2021

Marie Curie Ph.D. Grant, Marie Skłodowska-Curie Actions (MSCA), European Union

Jun – Nov 2018

Swiss European Mobility Program (SEMP) Scholarship, Yverdon-les-Bains, Switzerland

2012 – 2013

Scholarship for Academic Excellence, Community of Madrid, Spain

Professional experience

Aug 2023 – present

Global Health Biostatistics/Bioinformatics
GlaxoSmithKline (GSK), Tres Cantos, Spain

2019 – 2022

Bioinformatician – Ph.D. Student / Marie Curie Early Stage Researcher of ITN “Building a Gut Microbiome Engineering Toolbox for In-Situ Therapeutic Treatments for Non-alcoholic Fatty Liver Disease (BestTreat)”

Leibniz Institute for Natural Product Research and Infection Biology – Hans-Knöll-Institute (Leibniz-HKI), Group of System Biology and Bioinformatics (SBI), Jena, Germany

Sep – Nov 2020

Ph.D. secondment in industry

Clinical Microbiomics, Copenhagen, Denmark

Jun – Nov 2018

Bioinformatician master thesis student

Computational Intelligence for Computational Biology Group (CI4CB) at the School of Engineering and Management (HEIG-vd), Yverdon-les-Bains, Switzerland

2017

Data analyst intern

Philips Healthcare, department of Healthcare Informatics, Solutions & Services and Patient Care & Monitoring Systems, Madrid, Spain

Sep – Nov 2016

Biomedical engineer student intern

Unit of pediatrics endocrinology and diabetes, Biomedical Research Foundation of Ramón y Cajal Hospital, Madrid, Spain

APPENDIX

Appendix 1. Form 2 of the own contribution to the manuscripts

FORM 2

Manuscript No. 1

Short reference Ni, Qian, Siliceo, and Long *et al.*, (in press), Cell Metabolism.

Contribution of the doctoral candidate

Contribution of the doctoral candidate to figures reflecting experimental data (only for original articles):

Figure(s) # 3, S2, S5	<input checked="" type="checkbox"/>	Approximate contribution: 90%
Figure(s) # 2, 5	<input checked="" type="checkbox"/>	Approximate contribution: 70%
Figure(s) # 1, S6	<input checked="" type="checkbox"/>	Approximate contribution: 50%
Figure(s) # S7	<input checked="" type="checkbox"/>	Approximate contribution: 5%
Figure(s) # 4, 6, S1, S3, S4	<input checked="" type="checkbox"/>	0%

FORM 2

Manuscript No. 2

Short reference Chen and Siliceo *et al.*, (2023), Microbiome.

Contribution of the doctoral candidate

Contribution of the doctoral candidate to figures reflecting experimental data (only for original articles):

Figure(s) # 4, S2	<input checked="" type="checkbox"/>	Approximate contribution: 90%
Figure(s) # 3	<input checked="" type="checkbox"/>	Approximate contribution: 50%
Figure(s) # 1, 2, S1	<input checked="" type="checkbox"/>	Approximate contribution: 10%

FORM 2

Manuscript No. 3

Short reference Thielemann and Siliceo *et al.*, in preparation.

Contribution of the doctoral candidate

Contribution of the doctoral candidate to figures reflecting experimental data (only for original articles):

Figure(s) # 1, 3, 4, S3, S4, S5	<input checked="" type="checkbox"/>	100%
Figure(s) # 2, 5, S1, S2, S6, S7	<input checked="" type="checkbox"/>	0%

FORM 2

Manuscript No. 4

Short reference Leung and Long *et al.*, (2022), Science Translational Medicine.

Contribution of the doctoral candidate

Contribution of the doctoral candidate to figures reflecting experimental data (only for original articles):

Figure(s) # 2, 3, 4, S4	<input checked="" type="checkbox"/>	Approximate contribution: 5%
Figure(s) # 1, S1, S2, S3, S5, S6, S7	<input checked="" type="checkbox"/>	0%
